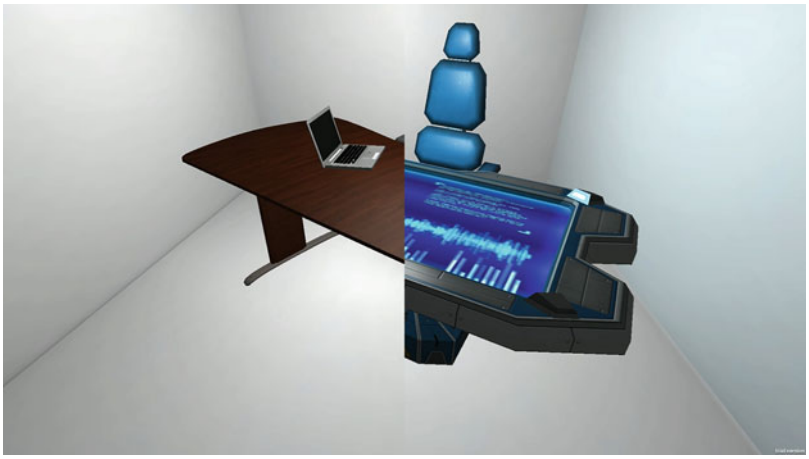
Substitutional Reality (SR) is a type of mixed reality addressing the disparity existing between a virtual environment and the physical environment in which the user is actually located. While university and professional Virtual Reality laboratories largely consist of empty rooms, especially in the context of domestic environments users are frequently surrounded with physical objects such as furniture, chairs, desks. These objects are not usually part of the virtual environment and might impede the user's experience. In this context, substitutional reality seeks to incorporate real physical objects in the virtual environment, by substituting them with mismatching virtual counterparts. This practice has been found to enhance the experience and believability of being in virtual environments.

Paul Milgram in his Reality-Virtuality continuum imagined a scale ranging from reality to pure artificial reality (Milgram and Kishino 1994). In this scale, we find the known concepts of Augmented Reality and Virtual Reality (VR). *Augmented Virtuality* (AV) is another concept which uses elements of the real world to augment a virtual environment, as opposed to Augmented *Reality*, which uses virtual elements to augment the real world. SR uses the physical objects present in the location a user wishes to experience VR to inform the design of a virtual environment.

The core principle of Substitutional Reality is to substitute these objects with virtual counterparts. This builds on the concept of "passive haptics," the idea of using closely matching physical objects as virtual proxies (Insko et al. 2001). SR differentiates itself on the premise of introducing a mismatch between the virtual object and the physical object acting as a proxy. If there was no mismatch, every substituted object would be a replica. Instead, by considering mismatching substitutions, the range of virtual environments that are possible to create is increased. A real desk in a *substitutional environment* might be substituted by virtual object of approximately the same shape and size, such as a futuristic "holographic table" or by a fantasy stone altar. In this way, if every object surrounding the user is substituted, the user will know that every object they perceive in the virtual environment can be touched (Fig. 1).

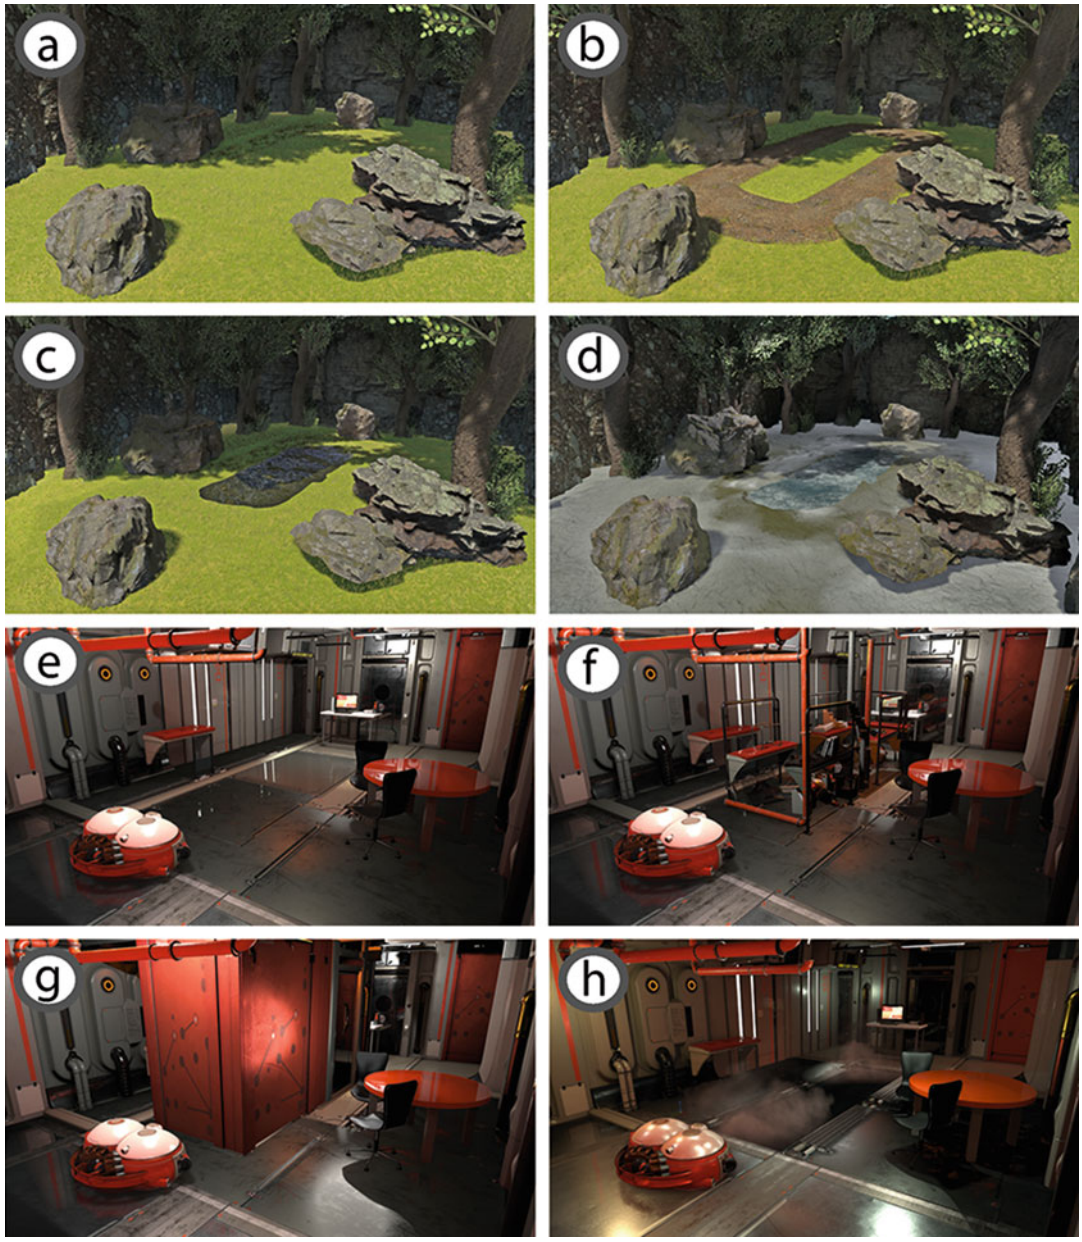
Research on SR first explored the question of how large can be the mismatch between a



Substitutional Reality, Fig. 1 In substitutional reality, physical objects are replaced by mismatching virtual counterparts to enhance the believability of the Virtual Reality experience. Simeone et al. 2015

physical object and its virtual counterpart, before it significantly affects the believability of the experience. In a study by Simeone et al. (2015), participants were immersed in a virtual environment. They were required to interact with a physical object, portrayed as a series of different virtual counterparts. The physical object (a common mug) remained the same throughout the duration of the study, whereas the virtual versions exemplified increasingly different types of alterations, for example, by altering its aesthetic qualities, where the shape and size of the object was kept unchanged but the appearance of the material changed (i.e. glass, wood). More extreme substitutions altered the size of the mug, or the affordances the object suggested. Each participant was asked to rate their experience of interacting with the objects in VR on a range of different factors, such as how much they believed they were interacting with the object they saw, how much the visual representation of the virtual object corresponded to the physical object they were holding, etc. Results indicated that participants could believe they were manipulating the virtual objects, depending on how much the part of the virtual object they were in contact with resembled the physical object's. This indicates that more extreme alterations can be applied to parts less likely to be interacted with. For example, participants believed they were manipulating an oil lamp, an object with a different function than the physical mug that was present in the study, as the oil lamp shared a handle with the real mug (Fig. 2).

The concept of substitutional reality can also be applied to other parts of a virtual environment. A follow-up study (Simeone et al. 2017) explored novel ways to subtly influence users' movement behavior while they are immersed in a virtual environment. Such methods can be useful in domestic environments, for example, to steer users away from fragile objects in their room or lead them towards areas where they can interact with physical objects. A study was devised in which participants were asked to reach three waypoints arranged in sequence in a triangular path. The shortest leg required them to cross a central area of the room (which was empty). Several virtual environments were created following the principles of SR. In these altered environments, the central area was substituted with either surfaces such as water or ice, which indicated that walking over them could be moderately discomfortable or dangerous, or with "immaterial" objects (physical objects that were not backed by physical proxies). The intention was to evaluate whether these alterations were sufficient to change the behavior of the participants, and lead them to take a different route avoiding those obstacles. If users correctly understand the properties of a (virtual) material, they will apply their real-life experience to it. Participants correctly interpreted the water as water and steered clear from it, whereas ice was mistaken as a rocky surface and they walked over it. Similarly, immaterial objects



Substitutional Reality, Fig. 2 The appearance of a virtual environment can affect users' movement behavior, provided that they correctly recognize its properties. Simeone et al. 2017

and walls were able to affect the path users took, even though they were aware that there was nothing in that part of the room.

These studies in the domain of Substitutional Reality inspired other researchers to continue exploring this space. The studies by Simeone et al. involved the manual authoring of virtual environments. Researchers have proposed systems capable of creating these Substitutional Environments automatically (Shapira and Freedman 2016; Sra et al. 2016). Other studies have investigated the design of dynamic props able to accommodate different virtual counterparts (Zenner and Krüger 2017; McClelland et al.

2017). Another direction focuses on the process of substitution itself, by proposing ways in which it might become more seamless (Valkov and Flagge 2017).

In summary, Substitutional Reality is still a developing field. It seeks to provide an answer to the challenge of experiencing VR in domestic environments. Rather than requiring users to radically rearrange the layout of a room to make space to accommodate a VR application, the physical objects in a room are incorporated in the design of the virtual environment, to augment the experience.

Super Mario Galaxy is a video game that is part of the Nintendo Mario franchise. This game was produced originally for the WII but was later made compatible with other Nintendo video game platforms.

Introduction

Super Mario Galaxy is a sequel in the Nintendo Mario franchise to the classic Super Mario 64 and the Mario Sunshine game. What sets this game apart from the previous games is not the 3D animation or the characters but the location where the story takes place. It is centered in deep space, bouncing from galaxy to galaxy, each with its own adventure. Due to this and other features, the game has sold more than 13 million copies and received some of the highest customer ratings for any Wii game (Cable 2020 and Goodall 2021).

The Popularity of Super Mario Galaxy

There is a myriad of things that set Super Mario Galaxy apart from its predecessors in the Nintendo Mario Franchise. The most noticeable difference is the environment in which Super Mario Galaxy takes place: space. This is important for several reasons. First, space is intriguing due to mysterious nature of the environment. Second, this allows the game developers to let their imagination run wild. The result was a large variety of planetoids and other space bodies with different themes. To tie these themes together into one game, the developers grouped the games into galaxies.

Super Mario Galaxy is also set apart by its mechanics. The traditional Mario mechanics were almost completely thrown out the window. The new mechanics were planetoids and Mario's new spin move. Due to the combination the game's 3D nature and planetoids, most of the time Mario is viewed from above instead of the side. This makes the normal stomp attacks very difficult to execute, so Mario was given a new tool in his arsenal: the spin move. This enables Mario to knock the enemies unconscious while remaining on the ground (Super 2021).

Although there have been many Mario games before and since Super Mario Galaxy, it is the first 3D game to have the feature that allows players to play as Luigi. Moreover, this Luigi character comes with a whole new range of challenges. Luigi is faster and can jump higher, with a disadvantage of being hard to stop and drifting while turning. This means that the players can essentially play the same levels twice while still playing a different game (Cable 2020).

SCAR and BAMS Analysis for Super Mario Galaxies

Let's begin with some definitions:

- BAMS Model – BAMS is an acronym for the four major monetary models that lead to the success of the esports industry (Collis 2020).
- Blades – The model in which subsidized platforms (consoles) capture market share to lock in long-term sales (game cartridges) (Collis 2020).
- Advertising and Assets – The model in which games are monetized like traditional sports through advertising and the sale of broadcast rights (Collis 2020).
- Microtransactions – An evolution of the blades model in which games themselves become the sales platform, generating revenue by selling incremental enhancements to their gameplay (Collis 2020).
- Subscriptions – A "magazine-style" revenue model, in which customers subscribe to a game by paying reoccurring fees (Collis 2020).
- SCAR Factors – SCAR is an acronym for the four major factors that propelled the rise of competitive gaming (Collis 2020).

Super Mario galaxy was marketed using the Blades in the BAMS model. Blades is the revenue model where platforms are subsidized in an attempt to lock in the long-term sales of the different games offered by the game manufacturer. This is similar to the way box cutters and blades are marketed. The box cutter is cheap, but the blades are what makes the products profitable (Collis 2020).

Super Mario Galaxy also exhibits many attributes in the SCAR factors. Skill wise, Super Mario Galaxy is not a game that is exceeding difficult to master. However, it is not easy to complete. It is a perfect balance of casual gaming and skill-based gaming. Therefore, it appeals to a much larger segment of players than games that are purely causal or skill based.

Community is another important factor in SCAR. Community is the support that a game receives from its creators and fans. Super Mario Galaxy has had a very large fan base. It is still popular today because of its fan and community bent on playing it even better than before. The accessibility of the game is another factor to consider. The game is very easy to get access to. It has been ported to new consoles such as the Nintendo Switch. The last SCAR factor is reward. Currently there is no large-scale competition for Super Mario Galaxy. Nevertheless, the game is suitable for speed running. There are several websites that

are devoted to just scores and times, so currently the rewards are just leaderboard based (Collis 2020).

Conclusion and Discussion

There have been many Mario games in the franchise since Super Mario Galaxy was released. In Super Mario Galaxy 2 that continued the galaxy storyline, Nintendo took many of the lessons they learned and implemented them in the new sequel (Gamespot 2020). Several of the power-ups from different 3D games are replicated in their new 2D platformers. They also discovered that multiplayer mode is a popular feature. This became evident in later games such as the New Super Mario 2D platformer on WII, which allowed four people to race through the levels and team up to discover new areas. Another popular feature is the central hub which was upgraded in Super Mario Galaxy 2.

In conclusion, Super Mario Galaxy is a great game that will be remembered for its contributions to the Super Mario franchise and the gaming world at large. Although Super Mario Galaxy was not the first 3D game released by the Super Mario Franchise, it was a significant steppingstone to improving 3D games. Super Mario Galaxy dared to go where no other Mario game had gone before: space. This allowed the developers to let their imagination run wild creating various galaxies with various themes and challenges. Many are still remembered to today in modern Mario games from the power-ups that existed in these galaxies. The game developers did not stop there. They introduced planetoids and Mario's signature spin move, which carried on to Super Mario Galaxy 2. The game also adopted the blades revenue model which made it the precursor to one of the most popular revenue models used by modern games today.

With the introduction of Super Smash Brothers Ultimate, the E-Sports scene evolved to adapt to this new iteration in the Smash Brothers series. The competitive fighting genre has held a strong position within E-Sports, and this new release solidified this claim. These two variables are inseparable. The Smash Brothers series continues to be a financial and commercial success. With this addition to E-Sports, the popularity of Smash and E-Sports begins to become more apparent with each passing day.

Definitions

Super Smash Bros. Ultimate is the fifth installment in the Super Smash Bros. series.

Super Smash Bros. is a series of fighting video games created by Masahiro Sakurai and published by Nintendo. The games primarily feature characters from various Nintendo franchises (See Fig. 1).

Nintendo Switch is a video game console developed by Nintendo.

The Announcement and Reception of Smash Ultimate

March 8th of 2018 may have been a normal Thursday for some. But, for a specific group of competitive players, March 8, 2018, was the day that has been long waited for. One of the largest videogame industries in the world broadcasted a video highlighting several videogames set to be released, with a surprise at the video's conclusion. In a matter of just 30 seconds, Nintendo stunned the world with its announcement of the fifth installation of the Super Smash Bros. series: Super Smash Bros. Ultimate. The 8th of March would be marked down in history, not only for Smash, but for E-Sports as well.

There is an overabundance of YouTube videos and Twitch clips covering this surprise announcement. The feedback was a mix of shock and horror (the good kind) and an overwhelming feeling of hype. Smash was back, but it was not alone. This new installation brought with it the biggest roster the entire Smash series has ever seen. Masahiro Sakurai, the creator of the Smash Brothers series, stated that every individual character in every Smash Brothers game would make a return; with some additional new arrivals. The roster has peaked at 80 playable characters, with some newcomers slated to be revealed soon in the Fighter Pass volume 2. This large selection of fighters – one of the largest of its kind – offers players a unique gameplay experience new to the Smash Brothers series. Players must always be vigilant and learn their matchups in order to achieve victory.

As of March 2021, Smash Brothers Ultimate had sold over 23 million copies across the world, marking it as not only the best-selling Smash Brothers game, but the best-selling fighting game ever! It has gone on to win awards such as the Best Fighting Game award at the Game Awards ceremony and the Nintendo Game of the

Super Smash Bros. Ultimate and E-sports, Fig. 1 Ultimate primarily features characters from various Nintendo franchises

Year award at the 2019 Golden Joystick Awards. Ultimate has been critically acclaimed from gamers and journalists alike. On the first day of the Nintendo Switch console's release, 26% of all Switch consumers played Smash Ultimate, naming Ultimate as the hardware that has accumulated the highest amount of sales during the Switch's release. It was also acclaimed as being the most preordered game in Nintendo's history, as well as being the most preordered Smash Brothers game.

Unique Gameplay Dynamics

With this new title, comes unique gameplay dynamics, both new and old. The most famous dynamic is called "tech," which is short for technique. There are different kinds of tech, but the "standard tech" is the most basic. This refers to the short window of time a player's character falls to the floor, and, while pushing the shield button at the right moment (roughly 8–11 frames in Ultimate), the character bounces up into the standing position immediately and negates all damage for a brief moment while getting up. New types of tech, such as footstool techs, can now be achieved. Previous techniques, such as buffering a tech during hitlag, have been brought back from previous generations of Smash. Another skill utilized in all smash games is called "DI." On the Smash Brothers Wiki, this is formally stated as being "the control the receiver of an attack has over their trajectory" (SmashWiki 2021a, b). This means that when the character is hit with an attack, and, by holding the control stick in certain directions during the freeze frames that occur from the attack, the character that was hit can slightly shift the direction they will soar when they are launched.

Competitive Tournaments and E-Sports

Perhaps the largest component that makes up a Smash Brothers game is its relationship with tournaments and E-Sports. The Smash Brothers series were designed to its core to be competitive games, whether it be in E-Sports or with a group of friends. Naturally, Smash Brothers Ultimate and its predecessors have held a position in E-sports tournaments since the first Smash game, but only around 2015 to the present day had it become truly cemented in modern E-Sports. With its newest release, Smash Ultimate has held a strong position in current E-Sports tournaments, such as EVO 2019, Super Smash Con 2019, and Genesis 6. Tournaments such as these are held all across the world, and they have great influence and impact on gamers and E-Sports as a whole.

Conclusion

Smash Ultimate was groundbreaking in terms of competitiveness and dynamics. Smash took the fighting formula and molded it into the ultimate fighting game. With the idea of skilled competition mixed with unique and fun gameplay in mind, Ultimate was able to break the boundaries of what E-Sports are all about. Its impressive roster and re-introduction of gameplay skills both new and old have cemented its position as the best Smash game, and one of the best E-Sports games. With its critical and financial success, Smash Ultimate has secured its place in video game and E-Sports history (Wired, 2018; The Higherlander, 2021).

Definition

Super Smash Bros. is a platform fighting game where the objective is to rack up percent (damage) on your opponents to knock them off screen.

Introduction

The history of the Super Smash Bros. series of games has been a grand and still progressing task that has no end in sight. This entry offers a brief summary of each of the Super Smash Bros. games in terms of development and competitive scene.

Super Smash Bros. (Nintendo 64: 1999)

Super Smash Bros. on the Nintendo 64 originally started out as a generic platform fighting game called *Dragon King: The Fighting Game*. The creator Masahiro Sakurai presented the prototype to his coworker Satoru Iwata who agreed to help with the project. Sakurai knew that his fighting game needed to include some famous Nintendo characters. Sakurai developed a prototype of the game with four of Nintendo's characters: Mario, Donkey Kong, Samus Aran, and Fox McCloud. The idea was approved, and the game began development and later released on January 21, 1999, in Japan and on April 26, 1999, in the United States. The game had eight playable characters right out of the gate with four hidden characters to unlock. Smash Bros. had a single player mode that played like other arcade games where you fight a handful of characters before you get put up against a boss and a couple other modes like break the targets and board the platforms. The game's focus was its multiplayer mode with four players being able to select their favorite Nintendo characters and duke it out. While this game was a massive breakthrough in fighting games, it is more of a historical piece that feels very clunky today, but this game created the foundation for what was to come out of the series.

Super Smash Bros. Melee (Nintendo GameCube)

Super Smash Bros. Melee is often praised as the best game in the series that had a very short development period. With only 13 months to develop the game, Masahiro Sakurai came back as director and wanted to make this "the sharpest game in the series." The game launched on November 21, 2001, in Japan and on December 3, 2001, in North America, and it was praised as one of the best games on the Nintendo GameCube. The game had 14 playable characters out the gate and 11 more to unlock with a total of 25 playable characters. The game had returned to single player modes and added new ones such as adventure mode, events mode, and homerun contest. While the single player mode is always fun, the multiplayer mode was considered the peak of the series. The game added a couple new inputs to give players even more options to attack and evade.

Super Smash Bros. Melee was and still is the most popular Smash Bros. game competitively in the series with a big player base and tournaments still going on today. The game is considered the fastest and most competitive Smash Bros. game to watch.

Super Smash Bros. Brawl (Nintendo Wii)

Super Smash Bros. Brawl started development without the creator Masahiro Sakurai even

knowing. Due to his departure from the game's original studio, Sakurai thought Melee was his last game in the series. However, due to Melees positive reception, Nintendo began development on Brawl when the Wii was first announced. Brawl was released on January 31, 2008, in Japan and on March 9, 2008, in North America. Super Smash Bros. Brawl had 39 playable characters with 2 of them being the first third-party characters in the series.

Brawl had a huge competitive scene in the beginning and quickly died down as the game was considered too slow for most competitors and it lacked a lot of the technical aspects that the previous game in the series had.

Super Smash Bros. 4 (Nintendo 3DS/WiiU)

Super Smash Bros. 4 began development in early 2012 and was going to be the first HD game in the series as well as the first Smash Bros. game for the Wii U and 3DS platforms. The game was released on the 3DS in October 2014 and then on the WiiU in November 2014. The game had a massive roster of 58 characters to play and new single player modes.

The game was considered not as fast as Melee and not as slow as Brawl but a good balance between the two. The game's competitive scene was very big on release, and many top players came to take the title as best in the world. However, one of the DLC characters – Bayonetta – began to plague the competitive, with her zero to death combos. As a result, the competitive scene began to die down quickly because many players believed that the game's characters were very unbalanced.

Super Smash Bros. Ultimate (Nintendo Switch)

Super Smash Bros. Ultimate did not have much information about its development. Ultimate started development when the last DLC fighters were coming out on Smash 4 in 2015. The main highlight of Smash Ultimate was that every fighter that has been in a Smash Bros. game is going to come back. Smash Ultimate reused a lot of assets from Smash 4 to make development smoother. The new game was released on December 7, 2018, and was considered as the best in the series. Smash Ultimate was launched with 74 fighters, 11 of those being new, and 12 more new DLC fighters were developed.

Ultimate brought a new single player mode called spirits and a revised classic mode that pits every fighter in unique scenarios that would fit those specific characters.

Smash Ultimate started out with a Nintendo-held tournament before the release of the game to show off its new mechanics and competitive aspects of the game. Smash Ultimate is considered the best modern competitive smash game whereas Smash Melee is still being considered by many to be the best in the series (Wired 2018; The Highlander 2021).

Symbolic Planning in Computer Games

Amol D. Mali
Computer Science Department, University of Wisconsin-Milwaukee, Milwaukee, WI, USA

Introduction

Symbolic planning refers to finding a plan containing actions by identifying actions relevant to achieving the specified goal and ordering these actions whose preconditions and postconditions (also known as *effects*) are explicit, by considering causal dependencies among them and avoiding conflicts. This distinguishes it from other kinds of planning in which actions or their preconditions or effects are not explicitly specified. Planning is different from scheduling. Planning involves selecting relevant actions and ordering them. Scheduling involves assigning start times and resources to preselected activities. Symbolic planning is relevant to all computer games in which interacting actions must be ordered or must occur in parallel, for a meaningful gameplay, such that the selection of actions and the type of their occurrence (sequential or concurrent) are based on reasoning about their preconditions and effects. Actions may be selected and ordered by a computer, or human player, or game designer, or action selection and action ordering may emerge during a gaming session. Symbolic planning can be used to verify that players can achieve goals with the available actions. It can be also used to identify if states from which a goal is not achievable can be reached. If such states exist, (i) the game design can be changed so that the states from which the goal is unreachable are unreachable, or (ii) new actions can be introduced in the game, and symbolic planning can be used to confirm that the goals are achievable using the new actions, and also provide relevant action orderings, if needed. Symbolic planning can also be used to identify the states of a game from which a goal is hard to reach, so that the game's design can be modified, to provide shortcuts to the player, if needed. Symbolic planning can be used to check if actions can occur concurrently without a conflict. Symbolic planning along with the estimated durations of actions and the estimated player-response times can be used to estimate the duration of a gaming session or a gaming episode. Symbolic planning can also be used in the design and control of the characters and objects which have no central role in a game and are included to mainly make the game interesting. An optimal planner finds a plan which minimizes the given objective function, like the total resource consumption or total execution time. Such traditional objective functions are not always suited for computer games because of the objectives of entertaining, educating, or surprising the player. This entry is a comprehensive survey of various ways in which symbolic planning has been used in computer games.

Terminology

Classical Planning: It is the problem of selecting and ordering directly executable actions, such that the actions can be executed in a manner consistent with the ordering, to achieve the given goal from the completely specified initial state, assuming perfect perception, deterministic actions, and a static and completely observable environment. Classical planning serves as the foundation for planning under uncertainty, e.g., conformant planning, probabilistic planning, and decision-theoretic planning.

STRIPS Planning: It is a special case of classical planning in which actions are instantaneous, the preconditions and effects of actions are pure conjunctions of function-free ground literals, and

there are no negated preconditions. If the execution of an action denoted by a' makes p true, then p appears in the list of *add effects* of a'. If the execution of a' makes q false, then q appears in the list of *delete effects* of a'.

Progression Planning: Also known as *forward state-space (FSS) planning*, it is a domain-independent approach to planning which finds a plan by generating a space of states beginning with the initial state, by applying actions until a state containing the specified goal is found. When progression planning is used to solve an instance of classical planning, all states generated by it are completely specified because of the assumptions of classical planning which prohibit any kind of uncertainty. Actions in the plans found by FSS planners are contiguous.

Regression Planning: Also known as *backward state-space (BSS) planning*, it is a domain-independent approach to planning which finds a plan by generating a space of states beginning with the goal, by applying actions until a state subsumed by the initial state is found. Actions in the plans found by BSS planners are contiguous.

Partial-order Planning: Also known as *least-commitment planning* or *causal-link planning*, it is a domain-independent approach to planning which finds a set of step-action bindings along with a partial ordering over the steps, such that the specified goal can be achieved by executing the actions bound to the steps in a manner consistent with the ordering over the steps. Steps are necessary to distinguish between multiple occurrences of an action in a plan. Since actions are not contiguous, it is possible to incorporate new actions in an existing plan if it becomes necessary due to changes, like a change in the goal which may occur between plan synthesis and plan execution. New actions can also be incorporated into the existing plan during its execution, if there is no conflict.

Causal Link: A causal link exists from a step denoted by s' to a step denoted by s" if s' is bound to an action which adds p which is also a precondition of the action bound to s", and the partial-order planner decides to use s' to supply p to s". s' is also known as the *producer* or *establisher* or *contributor* in this causal link. s" is known as the *consumer* in this causal link. This causal link is threatened if a step denoted by s'" can occur between s' and s" such that s'" is bound to an action which deletes p. Such a threat can be resolved by (i) including an ordering forcing s'" to occur before s', or (ii) including an ordering forcing s'" to occur after s", or (iii) including a new step denoted by s"" and binding it to an action which adds p and including a causal link in which s"" provides p to s", and including an ordering forcing s"" to occur after s'", and removing the causal link in which s' supplies p to s". Resolution (i) is also known as *promotion* because forcing s'" to occur before s' is like promoting it in the ordering of the steps for execution. Resolution (ii) is also known as *demotion* because forcing s'" to occur after s" is like demoting it in the ordering of the steps for execution.

HTN (Hierarchical Task Network) Planning: It is an approach to planning which uses domain-specific knowledge for speeding up plan synthesis, or for synthesizing a plan conforming to user intent, such that the domain-specific knowledge is provided in the form of HTNs. The tasks in an HTN may be primitive or non-primitive. A primitive task is not decomposable. Primitive tasks are actions. A non-primitive task is decomposed using primitive or non-primitive tasks. The specification of an HTN denoted by T contains a top-level goal which is achieved by choosing and ordering the actions that appear in the specification of T and/or the actions in the specifications of non-primitive tasks appearing in the decomposition hierarchy relevant to T. An HTN may also contain causal links and orderings over primitive or non-primitive tasks. HTNs make it possible to plan in a top-down fashion by comparing the goal of the given planning instance with the goals fulfilled by different HTNs provided for the planning domain, and selecting suitable HTNs, and selecting and ordering actions from their decomposition hierarchies.

Case-Based Planning (CBP): It is inspired by case-based reasoning (CBR). There is a library of cases such that each case in the library has the initial state and goal of a planning instance along with its plan and contextual information. When a new planning instance is received, the closest case from the case library is retrieved using similarity

criteria, and the solution from this case is adapted to solve the given instance. If there is no case in the library which is sufficiently close, the new instance is usually solved from scratch and a new case may be added to the library.

Symbolic Planning for a Consistent, Flexible, and Robust Gameplay

The narrative provided by an interactive narration system emerges from the interaction of the human player with the digital narration system. A symbolic planner is used in Shoulson et al. (2013) for finding a sequence of authored events which achieves the given goal configuration of objects and actors from their given initial configuration. There is a tradeoff between incorporating flexibility in interactive narration and the computational complexity of finding narrative plans. The higher the flexibility, the larger the worst-case search space for the narrative planner. Also, though giving a lot of flexibility to a narrative planner can result in surprising narratives, not all of these may be interesting to the human player. The narrative planner in Shoulson et al. (2013) searches in the space of sequences of events instead of the space of sequences of actions of individual characters. The former search space is much smaller. Event participants are autonomous between execution of events. The events are manually authored. An event consists of event behavior, event cost, the number of objects that can participate in the event along with their roles, precondition function, and postcondition function. The precondition function returns true if and only if the given objects can play the specified roles and also satisfy the authored preconditions of the event. The postcondition function changes the world state according to the authored postconditions of the event. The planner in Shoulson et al. (2013) can react to the user's actions and replan from the current state.

The importance of temporal issues in interactive storytelling is emphasized in Porteous et al. (2011). Some preconditions of actions need to be true over the entire durations of these actions, not just at the beginning. Some actions must occur in parallel for them to be meaningful in the game. The duration of an action is explicitly included in its description in Porteous et al. (2011). Furthermore, it is explicitly stated for each action precondition if it should be true at the beginning or end or the entire duration of execution of the action. Also, it is explicitly stated for each action effect if it is achieved at the start or end of the duration of the action. This action-description format is supported by version 3.0 of PDDL (Planning Domain Description Language) in Gerevini and Long (2005).

MIMESIS, a system for interactive storytelling, is presented in Young and Riedl (2003). Narrative planner is one of the components of its architecture. The narrative planner accepts descriptions of all actions that can be performed in the virtual world and the goal of the intended story, and searches the space of action sequences to find a story plan. The *discourse planner* accepts the story plan and the communicative actions to be used to convey the story. Communicative actions include narrative voice-overs, use of background music, and directives for a camera controller. Use of *narrative mediation* to handle an unanticipated activity of a user of MIMESIS is reported in Riedl et al. (2003). There are two kinds of narrative mediation: *accommodation* and *intervention*. Accommodation allows a user action threatening the precondition supported by a causal link or not achieving this precondition when in fact the user should perform an action serving as the contributor of the precondition, to occur, and changes the gaming world to make the deleted or unachieved precondition available for the consumer in the causal link. Replanning is a less preferred kind of accommodation as it can be computationally expensive. Intervention replaces the effects of the user action conflicting with the narrative with alternate effects that are compatible with the narrative. Intervention is essential when the user's action deletes a condition that cannot be added again. HTN planning is used in Cavazza et al. (2002) to find plans for individual characters for interactive storytelling. The tasks in their HTNs are totally ordered as in Nau et al. (1999).

Concurrent plan augmentation (CPA) is proposed in Elogeel et al. (2015). CPA involves identifying the ways in which a gameplay can deviate

from the intended execution of a tactical plan denoted by P', and coming up with a separate plan denoted by P" which protects the execution of P' by preventing deviations from P' or remedying the deviations from P', so that there are no damaging deviations. P' and P" are executed in parallel. CPA can be computationally cheaper and more reliable than replanning. The probability of failure of each action in P' is estimated using gameplay statistics. These probabilities are useful in finding plans that protect and remedy.

Symbolic planning is used in the design and implementation of the game master (GM) for role-playing games in Luong et al. (2017). The GM is responsible for setting up the game environment, managing the narrative flow, and enforcing the game rules. A tree containing goals, subgoals, and the actions for achieving them was manually created in this work, for the GM to use. Creating alternate plans for achieving a goal or subgoal is necessary for a flexible and robust gameplay.

Symbolic Planning for Incorporating Humor

It is reported in Olsen and Mateas (2009) that most humor in commercial computer games is language-based and hand-authored. They report on a system which models physical humor. This kind of humor arises out of funny motor actions. It is language-independent and culture-independent. They use HTN planning to find plans whose execution results in physical humor.

Symbolic Planning for Simulation

An approach to automatically populate virtual reality simulations with many characters is presented in Trescak and Bogdanovych (2017). They simulate agents' needs. Goals are automatically derived from these needs. They use case-based planning to find plans for agents. Though no game is reported in this work, such simulations can be gamified. Symbolic planning is used in Caruso et al. (2013) for generating data fast in a scalable and cost-effective manner. They generate plans for various goals related to the operation of smart homes. A valuable side effect of the execution of the synthesized plans is the data generated. Such data can be useful in building actual smart homes. Their approach has the following three stages: (i) Activities performed daily, like taking a shower and drinking milk in the morning, and optional activities like watching TV, are chosen along with the number of their occurrences, to generate high-level activity sequences. (ii) Planning instances based on the activity sequences from stage (i) and the available virtual environment are generated and solved, to have plans for completing the activities. (iii) The plans generated in stage (ii) are executed in the virtual environment, and measurements from the virtual sensors are collected. These measurements can be used to estimate the energy consumption in a smart home.

Symbolic Planning for Educating and Understanding Humans

A comparison of the conflicts in stories that are detected by people and the conflicts due to threatened causal links in these stories is reported in Ware and Young (2012). The latter conflicts can be found automatically. The goal of this study was to understand the differences between the human model of conflict and the computer model which treats a threatened causal link as a conflict. This understanding can be used to improve the design of computer games. Symbolic planning is used in Siddle et al. (2017) for generating plans for eating that are in compliance with or are violations of the recommendations for eating after a bariatric surgery. At logical level, the number of ways to violate health recommendations is exponential in the number of health recommendations when the health recommendations are independent of each other and cannot be split further into multiple health recommendations. Animations showing the execution of compliant and noncompliant plans for eating are created. The viewers of these animations answer questions about compliance and noncompliance. The viewers' responses are assessed, to rate their knowledge of the eating guidelines,

and to also evaluate the effectiveness of the 3D animations. There is no computer game reported in Siddle et al. (2017), but their implementation can be gamified, e.g., a human player can be given a chance to interactively change the eating plan being executed, and points can be awarded when the player enforces compliance by replacing any of the existing noncompliant choices by a compliant choice, and points can be deducted when the player violates any of the health recommendations by replacing any of the existing compliant choices by a noncompliant choice.

Conclusion

Symbolic planning has made important contributions to computer games. It has been useful for educating, entertaining, assessing, and understanding human players. The role of symbolic planning in simulations and serious games has potential to reduce costs, and save time and resources in real world. Still, the role of symbolic planning in many computer games has been described using only examples and case studies. This makes it difficult to formally evaluate the impact of symbolic planning on these computer games and provide guarantees.

Definitions

In tabletop storytelling, a 3D animated story is presented to the viewer as a hologram on a given plane in reality such as a tabletop. Every 3D animated story can be presented in augmented reality. Special augmented reality visualization techniques are required such as glasses or phones. The user becomes the cinematographer and can watch the story from the desired perspective. Moreover, simple types of interaction can be included to personalize the way the story is shown to the viewer.

Introduction

Storytelling takes place in various different formats. The most basic form is verbal storytelling during a conversation. Stories can be written text as well as illustrations only. Most of the time storytelling happens through a combination of mediums. The more accurate information is transmitted, the less room for interpretation of stories is left to the person that listens, reads, or watches a story.

Storytelling is an important factor for children growing up and it follows us through our journey of life. Through the history the methods of storytelling have evolved (Yılmaz and Ciğerci 2019; Kosara and Mackinlay 2013). Starting from mural paintings in caves, continued by verbal storytelling and finally written stories, modern everyday storytelling happens through images and videos. Tabletop storytelling uses holograms on top of physical surfaces for the purpose of visualisation. Tabletop stories can be narrated. They aim to present a completely natural way of watching a story similar to observing scenes in real world. Depending on the holographic rendering quality of the story and the device through which the story is consumed the degree of realism varies.

Holographic Content Creation

Tabletop storytelling offers two possibilities of scene setup: static and dynamic. In the static

theater setup, the whole scene is shown to the user all the time and the user can change the viewpoint depending on where the action happens. The user experiences a small-sized theater on a tabletop. In the dynamic setup, the scenes change throughout the story. During scene changes, the user needs some time to experience the new virtual environment.

Existing animated stories are transformed into a tabletop story. Stories consisting of animated 3D objects are converted into scenes such that the viewer can watch from every angle. Existing plays and movies are recorded using volumetric capture technology (Yu et al. 2021) to produce photorealistic tabletop stories.

Interaction

In tabletop storytelling, the viewers select the perspective in which they want to watch. Moreover, they have the option to modify content that appears in the story (Aurelia et al. 2014). In some stories they can change the appearance of characters and objects. In other stories they can even change how the story develops by choosing between multiple story lines (Li et al. 2022). The viewers' role ranges from passive observer to cinematographer, to director, and even to writer.

Presenting a Tabletop Story

Tabletop storytelling relies on artificial reality systems. A mixed reality system scans the physical environment the viewer is in and positions the story on a surface. Moreover, the viewer has the possibility to change the surface or place the story in the air. Depending on the device the viewer is using they see a 2D augmented or a holographic view of the story embedded into the environment. When using mobile devices such as phones and tablet computers, viewers see a 2D view of the story augmented on the tabletop. When using head-mounted mixed reality displays the tabletop story appears as a hologram. Stereoscopic displays (Lin and Woldegiorgis 2015) are placed on tabletops to present a 3D view of stories from somewhere within a 180 degree angle.

Conclusion

Tabletop stories provide an engaging way to consume content. In combination with volumetric recordings, they achieve a high degree of realism. It allows the viewer to have a tabletop-sized theater in their home which they can carry with them everywhere they go. Depending on the level of interaction a dynamic story allows the viewer to touch, grab, and move objects inside the story. For visualization, augmented reality mobile devices can be used. However, head-mounted displays offer a more intuitive holographic experience.

Definition

Tactile visualization is the process of formation of a mental image based on a sense of touch. In particular, objects for tactile visualizations can be created using 3D printers based on digital 3D models stored in a computer.

Introduction

The earliest data visualizations were, most probably, physical – built by arranging stones or pebbles and, later, clay tokens (Schmandt-Besserat 1999). Since then, many new technologies for fabrication of objects have been created. Currently, advances in rapid prototyping technology has allowed for the widespread of consumer level 3D printers. The accessibility of these printers allows us to demonstrate very sophisticated physical visualizations that were previously impossible. As a result, 3D printing becomes a very useful technology for creation of innovative educational material. Research has shown that spatial memory and object recognition are both accessed with tactile senses (Xiao 2011). However, since 3D printing for education is still at its infancy, there is no general approach to the creation of 3D-printed material. Specifically, the input data describing an interesting object or phenomenon can be converted into a 3D model via a number of approaches. Here we provide an overview of different methods for 3D conversion that take into consideration dimensionality of the initial data set (2, 2.5, or 3) and the source of the information (2D image, collection of 2D images, 3D scan). Next we discuss further processing and improvement of the output 3D model, such as fusion of multiple models and incorporation of additional information that can be used for improved 3D visual and tactile perception. Finally, we discuss transition from a 3D model to a 3D-printed object and describe pluses and minuses of currently available 3D printers.

State of the Art

One of the challenging steps in creating a tactile visualization is a conversion from the initial data source into printable digital 3D model. Figure 1 summarizes many possible inputs and data transformations all resulting in 3D printing. The input data comes in many different formats; thus, generation of a 3D digital representation can be time-consuming. We use various approaches depending on the data types and desired outcomes. For example, when working with scientific multidimensional images from such sources as computer tomography (CT) scans that are combined from a large number of 2D images, we use ImageJ and Kitware ParaView to define and generate isosurfaces (Rengier et al. 2010).

In the situation when only one 2D illustration or graphic needs to be converted into a 3D surface, then we need to use color information from the image to create depth or displacement maps. They can be later "extruded" in a computer graphic application or using specialized software. Next, the generated 3D surfaces are saved as polygon meshes.

Tactile Visualization and 3D Printing for Education, Fig. 1 Schematic of different approaches to 3D printing of tactile visualizations depending on the data input

After the creation of individual 3D models and corresponding meshes, the models can be further improved, combined, or enriched with additional information. Joining the models requires positioning and scaling the objects in a 3D virtual space. Multiple tools and techniques are used to further process, clean, and manipulate parts of the geometry in order to achieve accurate results. To

assist with this stage of the process, we use 3D computer graphic software, such as Autodesk Maya or an open-source application Blender. It is a critical step of the process, since it determines the final look and feel of the 3D model. The model is saved and then exported as either an.OBJ or. STL file. Prior to exporting the models into a 3D printing software (traditionally called Slicer), the models have to be analyzed, prepared, repaired, and processed.

Other approaches to the creation of 3D models include free-form modeling, surface scanning, and surface rendering must go through this same process in order to be 3D printed. For this task, we use either freeware Autodesk MeshMixer or an open-source software for processing unstructured polygonal meshes called MeshLab. These applications check the printability of the geometry and make the necessary repairs. Again, once the model has been properly analyzed, it is exported as an.OBJ or.STL and imported into the 3D printing software (Slicer).

The Slicer allows adjusting parameters of the printer directly affecting the final physical 3D-printed object. There are various Slicing software packages, each offering different customizing options. However, typical parameters include layer thickness, infill, and number of shells. Layer thickness is the resolution of the print and refers to the height that will form each layer of the print. Infill is the setting that determines the ratio up to which the object is going to be filled with the material (0 % means that the object will be completely hollow, and 100 % means completely solid). Finally, shells are used to strengthen and thicken the walls of the object.

Additionally, some printing software packages have settings for automating support structures for holding overhanging geometry, rafts for added support in holding the object to the 3D printer bed, and, in the case of multiple extrusion printing, selection that allows a 3D model to be printed using a specific extruder. The 3D Slicing software also allows for position models on a virtual 3D print bed showing actual size and helping to optimize orientation for better quality and faster printing.

3D Printing Hardware

There are many types of three-dimensional (3D) desktop printers. The majority of low-cost consumer 3D printers are FDM (fused deposition modeling), where objects are built up layer by layer with extruded melted plastic. The examples of materials currently used for 3D printing include such biodegradable plastic as polylactic acid (PLA), an environmentally friendly material derived from corn starch, and acrylonitrile butadiene styrene (ABS) polymer derived from fossil fuels. There are a number of transparent, conductive, wood, dissolvable, and other materials with advanced properties, including chocolate and biological cells that can be used for 3D printing. Some of these materials require specific hardware for extrusion and temperature control. Most of the polymers are produced as filaments with a diameter from 1.75 mm and 3 mm, depending on the printing head type. They melt at temperatures ranging from 170 to 250 degrees Celsius, and when they rapidly cool down, they form complex 3D objects, layer by layer. The cost of a consumer-grade, desktop 3D printer ranges from $300 for do-it-yourself (DIY) kits to $3,500 for pre-assembled, larger build area, systems. Many of them can be purchased on the Internet. Most 3D printers are compatible with standard.STL (stereolithographic) and.OBJ file formats.

As other forms of 3D printing based on stereolithography (SLA) become more accessible to the academic community other materials, such as metals, flexible polymers, and castable and high-stress resins become available. In the future, combinations of different materials together with the use of various advanced settings and improved resolution will ultimately lead to a higher quality and accuracy of tactile visualizations (Table 1). Additionally, this will allow using material properties, such as texture, elasticity, and thermal conductivity to encode and communicate more types of data in the same model (Padilla 2009).

For this study, we tested numerous 3D printers. We found that most low-cost consumer 3D printers have similar features, resolution settings, and overall output quality. However, during our

testing, we did find out that some printers were more consistent than the others. Typical problems with 3D printers include warping, lifting or shifting, and leveling/un-leveling of the print plate. The ability to maintain the appropriate temperature and jamming of the extruder were also problem areas for many of the printers. However, there were several that performed really well. For example, the Makerbot Replicator 2 4th-generation printers produced finished prints more often and had significantly fewer issues than many other models. This printer comes pre-assembled, uses PLA, and is equipped with a single extrusion nozzle. As of 2015, it ranges in price from $2199.00 to $2800.00 and can be purchased online.

Another example of a printer that consistently produced good results was the Rostock Max. This DIY printer uses a cylindrical mapping motion to build prints along the XZY axis. The printer has a heated build plate, large printer volume area, can print in PLA or ABS, and is a single-extrusion printer. The Rostock Max kit costs $1000.00 and took us 3 days to build. These two printers are just the examples of good-quality models that we tested, while there are many more available on the market.

In conclusion, we also found that different printers fit different departments and colleges. For example, engineering students liked the DIY printers because they allowed them to customize and modify the printer to their particular needs. Whereas students in other disciplines, such as the arts, liked the ease of use and available technical support of the preassembled printers.

Overview

Data visualization is a technique used to explore real or simulated data by representing it in a form more suitable for comprehension (Fritz and Bamer 1999). In schools and universities, most educators utilize generic two-dimensional scientific illustrations, and data visualizations. These graphics require students to mentally decode, rotate, and visualize the object, adding to the complex mental processing already taking place

through the introduction of new learning material. It is especially challenging when understanding requires complex geometric manipulations in three dimensions.

To decrease the cognitive load imposed on students and explain complex engineering, science, and art concepts easier, we are using tactile visualizations created with 3D printers. Tactile visualization, similarly to 2D data visualization, can be used as both explanatory and exploratory learning tools. Exploratory visualizations are used to better understand the data. Explanatory visualization is utilized as a method of communication to explain something about the data (Iliinsky and Steele 2011). Tactile visualizations allows for deeper explanation and exploration through providing physical representations that allow the learner to feel and touch the data, in addition to seeing. Furthermore, numerous evidence from educational psychology suggest that physical manipulative representations of complex objects facilitate understanding and learning (O'Malley and Fraser 2004). Additionally, building tactile data representations allows customizing and individualizing of educational material.

Our approach is to provide the students with physical and tactile representations of complex objects created by other people, as well as give them an opportunity to create tactile visualizations themselves. It helps more effectively and efficiently to aid in the development of mental images, transfer of prior knowledge to new context, improve mental processing, and positively contribute to learning experiences in STEAM (science, technology, engineering, art, and mathematics) education. We investigated and categorized multiple approaches to the creation of tactile visualizations for numerous departments: Computer Science, Paleontology, Geology, Chemical, and Biomedical Engineering from the College of Arts and Sciences and College of Engineering, as well as the Colleges of Education. Furthermore, we see educational value in the use of tactile visualizations for the learners with special needs and disabilities. In particular, tactile visualizations can greatly enhance education of visually impaired students.

Experiments and Showcases

In the following section, we show some of the approaches that were utilized to generate tactile visualizations for several educational modules. The design and results of the tactile visualization depend on the data types, subject area, 3D printing hardware, and materials utilized, as well as the desired outcome in terms of educational goals and objectives.

Our first example demonstrates the approach to creation of tactile visualizations from a single 2D image. Here we used a high-resolution photograph of a micropolymer structure, taken with a camera mounted on top of an optical microscope (Fig. 2a). The photograph was processed and converted to a gray-scale image using Adobe Photoshop. Then a simple 3D polygon mesh was created in Autodesk Maya. This polygon mesh was further modified to allow the gray-scale image to fit and wrap appropriately to a surface while maintaining the accuracy of the gray-scale image and avoiding distortion during the transfer process. The gray-scale image was then mapped into a polygon mesh as a displacement map texture. Once the polygon mesh displacement was set, both elements were combined into a single-polygon model (Fig. 2b). The model was then analyzed and optimized further using MeshLab, before being imported to the Slicing software for 3D printing using the Makerbot Replicator 2, 4th generation printer. The final print (Fig. 2c) is 2 in. by 1.5 in. and is printed in white PLA with 100 μm resolution. This is a great example of a tactile visualization that can be used for visually impaired students. While normally they would not be able to see details in 2D image, they will be able to learn information about this complex structure encoded into rich surface topography.

The next example describes Biomedical 3D visualization that was created from 2.5D input (by 2.5 input we mean a collection of 2D images). In this scenario we started with a dataset of computer tomography (CT) images (axial, coronal, and sagittal Planes) of a human heart. The images were combined and processed in ImageJ and Kitware ParaView. Once the image stacks were

created, an appropriate threshold value was set for the selected areas. The selections were then used to generate volume renderings that were further analyzed, processed, converted to a three-dimensional polygonal surface, and exported as an.OBJ file. The.OBJ file was then imported to Autodesk Maya and MeshMixer for repairing and cleaning (Fig. 3a). The final model was sliced and printed on both the Makerbot Replicator 2, 4th generation, and Form1+ 3d printers (Fig. 3b). The final tactile visualizations were 3D printed using multiple materials including, PLA, ABD, dissolvable, and photopolymer resin (Fig. 3c). Biomedical students were directly involved in the creation of this visualization and as a result were able to build a better understanding of multidimensional data and medical image processing. Furthermore, the tactile visualization allowed the students to understand better the complex anatomical structure of a human heart.

Our final example demonstrates the use of both 2D image and 3D surface scan data as starting points for the generation of the 3D printing of tactile visualizations. Here we worked with computer science students to compare 3D surfaces generated from a 3D scanner to an algorithmically/programatically generated 3D surface created from two 2D images of a bull.

To build a 3D model from a 2D image, a custom program was written using OpenCV and OpenGL. The combined images generated a 3D polygonal mesh. The mesh was then repaired, processed, and sliced for 3D printing. The same bull that was photographed was also surfaced scanned using a NextEngine 3D Laser scanner. A point cloud was generated, cleaned, and then converted to a polygon mesh. The mesh was saved as an.OBJ file and then imported to MeshLab for further repair and processing. Once the model was ready for 3D printing, it was imported to the slicing software. Here, for both prints, we used KisSlicer. The settings and materials were also the same, as we wanted to conduct a direct comparison. Both models were printed several times on various printers; however, the initial models were printed on the FlashForge Creator Pro in ABS. These tasks allowed the computer science students to grasp not only multiple techniques for creating three-dimensional computer graphics but also the ability of tactile

visualization in comparing and measuring the accuracy and detail through touch and physical rotation of 3D-printed models. The final result in comparing the models generated from an image and a 3D scan revealed that the scan was much more efficient and accurate in producing printable surfaces. However, even though it was expected, it was still a great educational experience, since the students learned a lot about different data input types (Fig. 4).

Conclusion and Discussion

Tactile visualization using 3D printing is an emerging area of research that examines how computer-supported, physical representations of data can enhance cognition, communication, learning, problem solving, and decision-making. Since tactile visualization is a new area, there is a lot of potential to develop it further and find new exciting applications.

Other interesting future directions include combining tactile visualization with a gesture control and tracking and touch-responsive and tangible user interfaces (TUIs) (Ishii 2008). They offer not just the ability to touch but also provide tangible force feedback and interactive audio output. Another approach is combining 3D printing, electronics, and microcontrollers, such as the open-source platform Arduino (Arduino 2015). The use of 3D-printed models and augmented reality displays might also be combined with data types to provide a more immersive experience for interactive data manipulation.

To summarize, tactile visualization combined with other new technologies can completely transform education and create new, more efficient, and enjoyable learning experience.

Definition

The surface-based interactions concept denotes a transparent spatial tracking approach for enhancing user interactions with physical objects and surrounding environments. It constitutes surface-based interaction models encapsulating multi-dimensional position and orientation tracking that enriches human-computer interfaces with augmented interactions and support for natural, self-explanatory components and semantics.

Introduction

In everyday life, people often refer to nearby objects by pointing gestures. In a shop, customers

point to products they want to buy, in a library to books they want to borrow, and in an office to documents they need. Such pointing or showing gestures are quite convenient and greatly facilitate communication between humans in a natural way. It is much different, however, when an automated system processes human requests. For example, at a self-service cash register, showing the goods to be purchased is not sufficient as each product must be appropriately oriented and placed in front of a barcode reader for scanning.

Being able to directly point anywhere on a physical object and get an identifier irrespectively of its position and orientation would be very useful. For this, instead of a single barcode, an encoding that covers the entire object surface could be applied (Kanev and Kimura 2005–2010, 2011). Similar to barcodes, a surface code applied to the object could return an object identifier for instant access to a repository where the price is stored (Kanev and Mirenkov 2010). In addition, information about the orientation of the object with respect to the scanner could also be extracted and employed, for example, for spatial queries (Bottoni et al. 2015).

Similar pointing functionality is used for interacting with screen-based representations of virtual reality (VR) models and nearby physical objects through VR and augmented reality (AR) applications (Xiao et al. 2018). High-quality AR integrates the virtual and physical components in a seamless way and ensures their synchronous presentation on the screen (Hamza-Lup and Rolland 2004). This, however, is a computationally expensive process that requires reliable recognition and simultaneous tracking of physical objects in real time (Wang et al. 2007; Nuchter 2009).

The surface-based interaction approach that we discuss in the following sections greatly reduces the computational burden since it facilitates the recognition and tracking of the physical objects by processing the digital codes on their surfaces (Kanev et al. 2007). In this way, instead of complex scene analysis and object recognition, just extracting and decoding the embedded digital information will suffice for the object identification and tracking (Kanev et al. 2008b).

Design and Implementation Summary

Let us consider some printed material such as a book and a surface code covering all of its pages. The surface coordinates of the book can be defined as page numbers followed by 2D positions on the page (Kanev and Mirenkov 2010; Signer and Norrie 2007). Such surface coordinates can be used for linking to multimedia content by invoking, for example, related hyperlinks (Barneva et al. 2009a). Global mapping of book coordinates to hyperlinks can be implemented through unique identifiers such as International Standard Book Number (ISBN) embedded in the surface code and distributed over the document surface.

Digital surface encoding can be applied to surfaces of physical objects by employing adhesive labels with preprinted digital codes (Kanev 2008). For direct digital encoding of object surfaces, physical engraving and laser marking can be used (Kanev et al. 2012b; Mizeikis and Kanev 2016). Objects with embedded surface encoding can also be produced by employing 3D printing and other manufacturing technologies (Kanev et al. 2015).

At larger scales, digital surface encoding can be employed for encoding walls of entire rooms (Saito et al. 2007; Kanev et al. 2012a). A mobile robot equipped with a digital camera and appropriate decoding software will then be able to precisely track its position and orientation with respect to the walls of such a digitally enhanced room (Barneva et al. 2013). Since position determination is based on extracting and decoding wall patches of limited sizes, it can be carried out even in cases of partially covered walls and objects obstructing the robot view (Kanev et al. 2010).

Specialized Surface Encodings

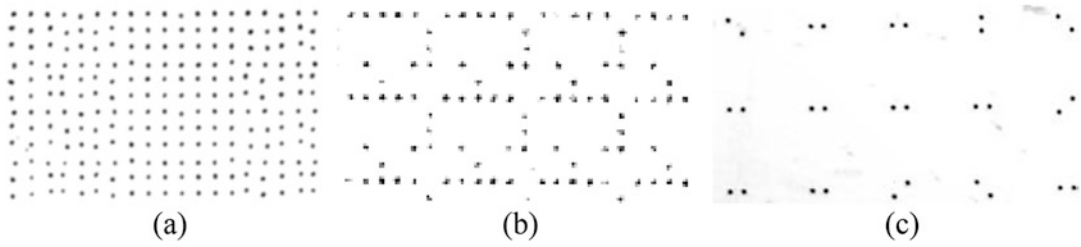
Uniform surface encoding with minimal ink coverage and sufficient redundancy for fast and reliable coordinate extraction requires codes with special properties (Barneva et al. 2009b; Kanev and Kimura 2006a; Pettersson and Ericson 2007). Such codes should allow for minimal alteration of

the encoded surface and the superimposed content (Fig. 1). In contrast to traditional barcodes, surface codes have no visible markers and block boundaries, thus encoding units must be identified by other means (Hecht 2001; Pettersson 2006).

With respect to this, some theoretical issues of cluster pattern interfaces (CLUSPI) and related surface-encoding approaches are presented in Barneva et al. (2009b). The discussed CLUSPI codes are optimal in the sense that coordinates are encoded with a minimal possible number of bits, and since codes of adjacent coordinates differ by a single bit, code transparency can be significantly increased by the reuse of neighboring bits (Golomb et al. 1982; Kanev and Kimura 2011).

Using a Cartesian coordinate system, any rectangular surface area can be covered with a square grid and enumerated with two coordinates as shown in Fig. 2a. Each pair of integers denotes the x and y coordinates associated with the corresponding grid cell, e.g., (1, 2) stands for the coordinates $x = 1$ and $y = 2$. Depending on the desired area size, the employed coordinates can be confined to a specific range of integer values that can be binary encoded with a predetermined fixed number of bits. We can therefore define an *optimal coordinate code* that will differ by a single bit when encoding any two adjacent coordinates, as depicted by the dashed rectangles in Fig. 2b. Note that there is no room for further optimization, since any two adjacent coordinates are different so their encodings must also be different and therefore they must differ by at least one bit. When such an optimal code is employed for linear encoding, most of its bits may overlap so they can be reused as shown in Fig. 2c. In this way, we effectively encode each linear position by a single bit, while we can still use as many adjacent bits as necessary to construct a code of any size (Golomb et al. 1982; Kanev and Kimura 2011).

In Fig. 3, we show a sample bit sequence S that can be used for 9-bit coordinate encoding within



Tangible Surface-Based Interactions, Fig. 1 Specialized surface codes with no visible markers and block boundaries. Note the decreasing dot density from left to right (**a**–**c**) that improves the code transparency and thus helps reduce the visual impact on the overlaid content

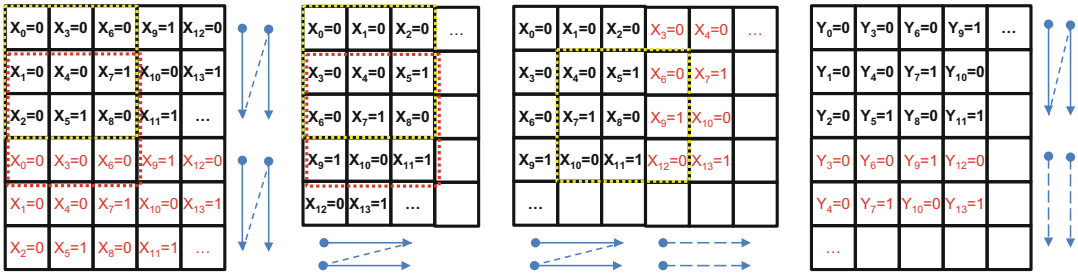
Tangible Surface-Based Interactions, Fig. 3 The bit sequence S consisting of unique 9-bit subsequences. The red, highly elongated rectangle depicts a subsequence of 9 consecutive bits [63~71] that is suitable for coordinate decoding. The better-shaped blue rectangles, however, enclose subsequences of nonconsecutive bits that are not suitable for coordinate decoding



Tangible Surface-Based Interactions, Fig. 4 Area filling coordinate placement by ribbon folding in horizontal ((**a**) and (**d**)), and vertical ((**b**) and (**c**)) directions. The ribbon replication in y-direction (**a**) and the coordinate extensions in x-direction (**c**) and in y-direction (**d**) are shown in red

the range [0, 512]. The sequence S is constructed in such a way that any bit sequence of length 9 (except the sequence of 9 zero bits) appears exactly once as a subsequence of the sequence S. Therefore, any given 9-bit sequence could be associated with a unique offset determined by the position of its first bit in S. We will use the so defined offsets as coordinate values.

For proper coordinate decoding, we need to extract subsequences of 9 consecutive coordinate bits from the sequence S so we will seek surface bit placements that facilitate this process. The bit placement shown in Fig. 3 is clearly not quite suitable since the coordinate decoding would require imaging of highly elongated 1×9 rectangles (e.g., the red rectangle in Fig. 3) that significantly diverge from the typical camera views. Note that the better shaped rectangles shown in blue in Fig. 3 do not contain consecutive bits, e.g., [10~14, 73~77], [20~22, 83~85, 146~148], and [30~31, 93~94, 156~157, 219~220] for the rectangles from left to right.

If the coordinate bits are ribbon-folded as shown in Fig. 4a, however, some improvement can be achieved. Indeed, as depicted in Fig. 4a, the extracted bits are consecutive when the starting bit is on a row divisible by 3, e.g., the bits [0~8] in the yellow rectangle, but the bits will not be in order when the starting bit is on any other row, e.g., the bits [1~2, 0, 4~5, 3, 7~8, 6] in the red rectangle. In contrast, the ribbon-folding shown in Fig. 4b is free of the above defect as it always produces the coordinate bits in proper order, irrespectively of the position of the starting bit (compare the bit sequencing in the red rectangles in Fig. 4a which is not in order and in Fig. 4b which is in order).

The ribbon-folding in Fig. 4b might look contrary to the common sense, since our original intent was to encode the x-coordinate going from left to right, while in this ribbon-encoding, we went downwards and encoded a stripe in y-direction, leaving most of the surface to the right empty. Fortunately, it is easy to fix this by just extending the bit sequences from the stripe to

the right as shown in Fig. 4c. Now, with the entire surface overlaid with bit-encoded x-coordinates, it becomes clear that a sequence of 9 consecutive coordinate bits can be conveniently extracted starting at any surface position by examining a 3×3 square area, e.g., as shown by the yellow rectangle [4~12] in Fig. 4c.

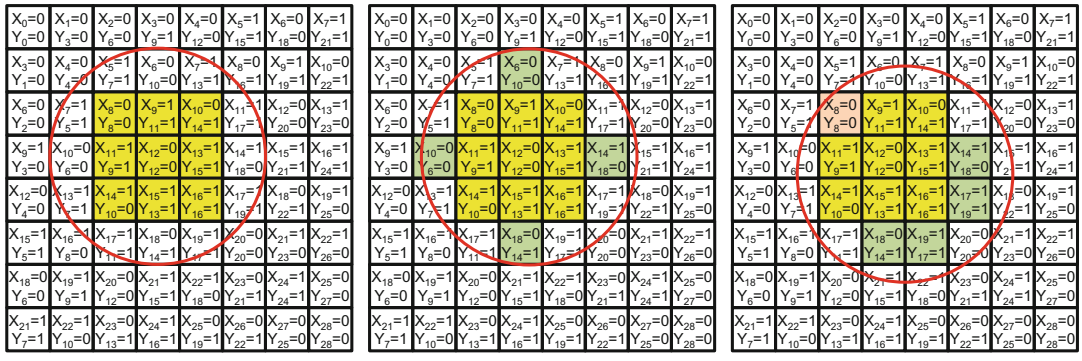
Note that the y-coordinates can be encoded in a much similar way. In this case, we start at the top left corner and fill the first three rows as shown in Fig. 4d. Then, we extend the bit sequences downwards, as depicted in red.

Our objective is to ensure reliable coordinate bit extraction and decoding irrespectively of the camera rotations related to the encoded surface. To account for this, in the following considerations, the typical camera view will be approximated by a sufficiently large circle, centered at the camera focal point as depicted in Fig. 5a. The diameter of the circle is set to five grid units despite that only 3×3 grid units would be required for the coordinate decoding. In this way, we ensure that a sufficient number of bits will be accessible for any displacement of the circle over the encoded surface.

When the camera view is centered in the middle of a grid cell as shown in Fig. 5a, a 3×3 cell area containing consecutive bits suitable for both x- and y-coordinate decoding can be extracted. When the camera view moves to the right, an additional grid cell comes into the view, e.g., (X_{14}, Y_{18}) in Fig. 5b. In a similar way, additional cells appear in the view when the camera moves into up (X_6, Y_{10}), down (X_{18}, Y_{14}), and left (X_{10}, Y_6) directions. When the camera moves diagonally, e.g., simultaneously down and to the right as shown in Fig. 5c, the cell (X_8, Y_8) disappears from the view, while four new cells, namely, (X_{18}, Y_{14}), (X_{19}, Y_{17}), (X_{17}, Y_{19}), and (X_{14}, Y_{18}) appear in the view. The obtained additional bits either overlap with some of the consecutive bits in the subsequence (e.g., X_{14} and Y_{10} in Fig. 5b) or can be used to extend the length of the subsequence (e.g., $X_{17} - X_{19}$ and $Y_{17} - Y_{19}$ in Fig. 5c).

Indeed, when moving the camera to the right at larger distances, some lower bits from the sequence will disappear from the view while other higher bits will instead appear in the view, which is consistent with the coordinate value increasing when moving to the right. Further on, as shown in Fig. 5, most of the peripheral bits that are close to the edges of the camera view are either replicated or replaceable by other higher or lower bits. This is consistent with the optical properties of the traditional camera input, where the highest quality view is obtained in the central area while most of the distortion is in the peripheral area.

To take advantage of the replica and substitution bits, we introduce *virtual blocks* that are



(a) (b) (c)

Tangible Surface-Based Interactions, Fig. 5 The camera is centered in the middle of a grid cell (**a**), moved to the right (**b**), and moved diagonally in right-downward direction (**c**). Yellow depicts the core cells, green the cells that enter the camera view, and red the cells that move out of the camera view

Tangible Surface-Based Interactions, Fig. 6 Virtual blocks of different shapes containing valid sequences of 9 bits for decoding of x-coordinates (**a**) and y-coordinates (**b**). In (**c**), the x-axis is shown in blue and the y-axis in red

defined as valid sequences of 9 consecutive bits irrespectively of their placement on the encoded surface, as shown in Fig. 6.

Note that these virtual blocks do not have any predetermined shapes, sizes, or placements, and that they can even overlap. The virtual blocks are just a way to access the coordinate encoding bits in an efficient and well-organized manner, while ensuring access to the necessary replica and substitute bits for corrections through redundancy and error recovery.

While we have placed all coordinate bits on a Cartesian coordinate system, the surface coordinates of our encoding are not necessarily Cartesian. Indeed, if we connect some starting positions that will decode to the same x-coordinate (X_7), as shown in Fig. 6c, we will obtain a line that is parallel to the y-axis. Doing the same for some starting positions that will decode to the same y-coordinate (Y_9), we can obtain the direction of the x-axis. Now it becomes clear that the encoded coordinates are given in a skewed coordinate system that is different from the initially chosen Cartesian coordinate system. The relationship between the decoded (X, Y) pairs and the corresponding row (R) and column (C) numbers is as follows:

$$X = C + 3^{*}R$$
$$Y = 3^{*}C + R$$

After solving for C and R, we obtain:

$$C = (3^{*}Y - X)/8$$
$$R = (3^{*}X - Y)/8$$

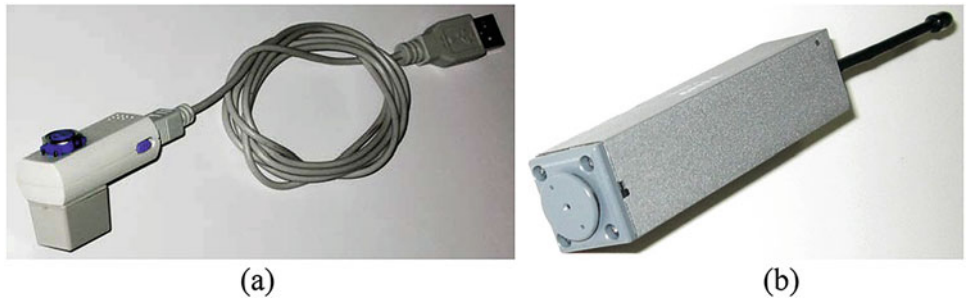
The above expressions allow for direct conversion of decoded (X, Y) coordinates to surface coordinates (R, C) expressed in row and column numbers.

Due to the above discussed special properties of the employed coordinate encoding bit sequences, no redundant encoding is required for recovering individual damaged or missing coordinate bits (Brimkov et al. 2020). Redundant encoding may be useful, however, in case multiple missing or damaged bits need to be recovered (Kanev and Kimura 2005–2010).

Applications and Implementation Examples

The direct-point-and-click functionality for printed materials (Kanev and Kimura 2006a) can be implemented through inexpensive handheld image acquisition devices. The compact surface code reader in Fig. 7a, for example, is based on a simple off-the-shelf Universal Serial Bus (USB) camera, while the device shown in Fig. 7b is based on a mobile wireless camera.

The more advanced optical code reader shown in Fig. 8a, on the other hand, functions as a digital microscope and supports the inspection of a wide range of surface under different magnifications



Tangible Surface-Based Interactions, Fig. 7 Optical code readers based on a simple off-the-shelf USB camera (**a**) and a mobile wireless camera employed as a surface code reader (**b**)

and light wavelengths (Kanev et al. 2008b). As shown in Fig. 8b, dial controls are provided for the brightness, and the zoom and the focus. The lighting unit on the front of the optical reader incorporates infrared, visible light, and ultraviolet LEDs, and accepts wavelength filter attachments for controlling the lighting conditions of the inspected surface.

Employing such surface code readers allows for interactions with digitally enhanced paper documents that provide more intelligent support for reading (Fig. 9) through instant access to linked digital content (Kanev and Orr 2006).

This approach is particularly suitable for mathematical documents where highly specific references are needed (Kanev et al. 2008a). As shown in Fig. 9, the reference embedded in the sample mathematical document denotes not only the source document (EKO03) but also a specific component in it (Lemma 3.2). Such references, embedded in mathematical documents, can be overlaid with surface encoded patches as shown in Fig. 10a and used for direct point-and-click access to the referred specific document components as shown in Fig. 10b.

Specific applications have been developed for language learning (Gelsomini et al. 2020), including sign languages (Kanev et al. 2009–2010). In Fig. 11a, we show some sample digitally enhanced printed content for Japanese learners of English. The point-and-click interactions with the content allow for pronunciation in native English and translation into Japanese of the highlighted words, as well as reading and translation of entire sentences. This approach has been extended to other languages by providing direct point-and-click access to a multimedia dictionary that supports a multiplicity of languages. In addition to the text-based point-and-click interface, the multilingual dictionary is also accessible through an image-based interface employing language neutral icons, as shown in Fig. 11b.

A more general approach for computer-assisted human interactions with the surrounding world that are based on ubiquitous surface encoding of physical entities and backgrounds has been discussed in Kanev and Mirenkov (2010). It introduces a more general concept that allows direct, real-time access to computer-based multimedia information through printed interfaces, which is further extended to active knowledge semantic surfaces for ubiquitous direct interaction environments with self-explanatory components. The implemented framework incorporates a code attachment system (CAS, Fig. 12a)

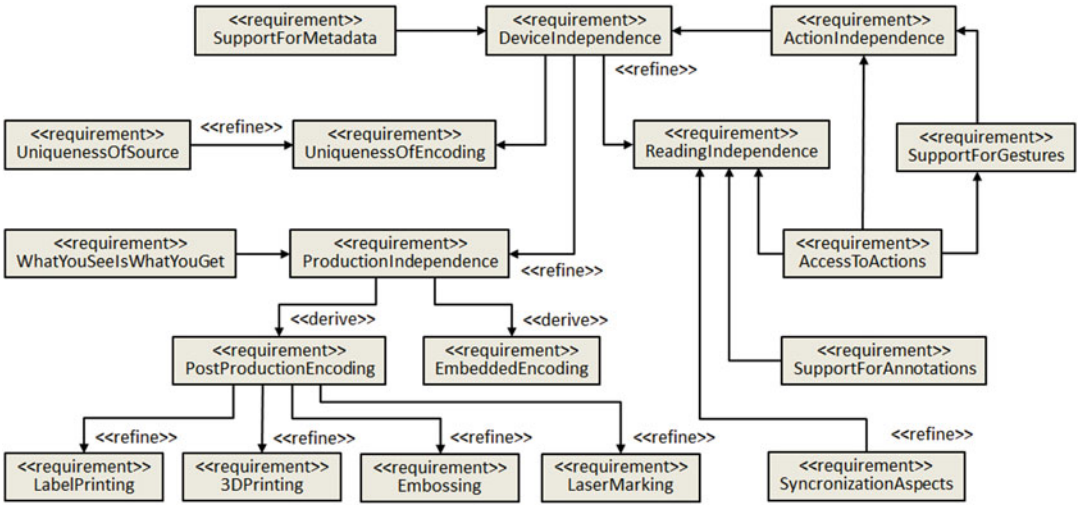
The point-and-click functionality and the semantic surfaces concept have played an important role in the design and development of the more general framework for constructing collaborative surfaces through augmented documents and objects (Bottoni et al. 2013). More details about the employment of the framework for situated interactions expressed via UML profiles are provided in Bottoni et al. (2015). For illustration, a diagrammatic representation of relations among requirements for the augmented surface framework, supporting digital encoding of physical surfaces through traditional and 3D printing, embossing, and laser marking is shown in Fig. 13.

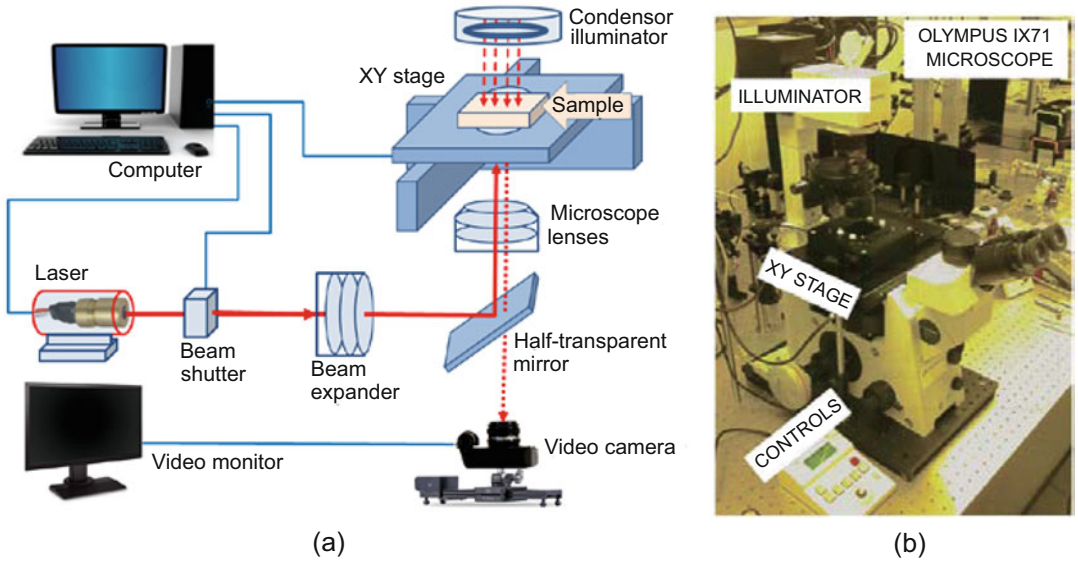
The framework for situated interactions has been extended to integrate the employment of physical objects as tangible interface components (Kanev 2012) and the concept of tangible technology enhanced learning (T-TEL) (Boytchev et al. 2012), and has been employed in later works related to technology enhanced collaborative surfaces for the next-generation classroom (Barneva et al. 2017). Based on this, applications for collaborative storytelling in T-TEL language

learning (Gelsomini et al. 2018a) and for Kanji learning in tangible AR settings (Gelsomini et al. 2018b) have been developed.

While surface encoding of physical objects is possible through printed labels, technologies such as laser marking (Gnatyuk et al. 2011; Diaci et al. 2011) allow for more robust and durable encodings. With respect to this, results of particular interest have been obtained for subsurface digital encoding of semitransparent substrates (Kanev et al. 2012b; Mizeikis and Kanev 2016). A schematic diagram of the experimental system for subsurface laser marking and a photo of the employed equipment are shown in Fig. 14.



Tangible Surface-Based Interactions, Fig. 13 Relations among requirements for an augmented surface framework supporting digital encoding of physical surfaces through traditional and 3D printing, embossing, and laser marking



Tangible Surface-Based Interactions, Fig. 14 Schematic diagram of the experimental system for subsurface laser marking (**a**) and a photo of the employed equipment (**b**)

This system provides support for encoding of digital information in plastic objects using embedded bulk marking by tightly focused pulses of an infrared nanosecond laser. The marking consists of a machine-readable pattern of laser damage spots in the subsurface region of the object. Compared to surface marking by printing or laser ablation, this method presents the advantage of improved durability of the code. Some sample physical objects, digitally encoded through this method are shown in Fig. 15.

Instead of applying digital encoding to existing physical objects, in some cases, it may be desirable to incorporate the encoding into the object production process. As illustrated in Fig. 16, the 3D printing process allows for direct creation of such digitally encoded objects (Kanev et al. 2015).

With respect to large-scale surface encoding, work has been done on surface-based spatial awareness for mobile robots (Kanev and Kimura 2006b), environmental codes for autonomous position determination (Kanev et al. 2012a; Barneva et al. 2013), encoding of surfaces for global positioning and navigation (Kanev et al. 2010), and more generally on direct-access pattern interfaces for geometric networks (Brimkov et al. 2016). In Fig. 17, we illustrate the production of digitally-encoded wallpaper for global positioning and navigation and the consecutive extraction and analysis of the embedded environmental codes.

Conclusions

While tangible surface-based interaction approaches may employ common methods for code processing and position determination, the actual surface encoding parameters depend on the specific application requirements. On the one hand, small objects observed from closer distances require fine encoding patterns that are practically invisible to the naked human eye. On the other hand, large-scale surface-encoded walls, and other interiors require aesthetic surface coverage that accommodates the necessary digitally encoded data without disturbing the appearance of the existing visual patterns. This was reflected in the wide spectrum of applications and related technologies for the physical embodiment of the surface codes covered hitherto.

Definition

Computer graphics classes teach the theory of making graphics and have students use existing graphics tools to make graphics. As an example, students in a computer graphics class learn about making graphics and products (letterhead, business card, brochure, website) with those graphics to create and express a brand.

Introduction

Computer graphics classes in the past revolved around the mathematics and programming for making tools that can be used to produce graphics and even had students write parts or components of software tools that make graphics. Today, the need has shifted to be good producers of the graphics content rather than the tools. Many graphics tools either require a sense of computer programming (e.g., Adobe Flash) or scripts, and small programs can be combined with graphics to create interactions in movies and games.

In this entry, what is currently included in computer graphics classes is reviewed, and a specific computer graphics class is described with example assignments from students at St. Mary's University in San Antonio, Texas (St. Mary's University 2015). The class has been taught over the last 6 years in the current format, about every year and a half from computer science department.

The St. Mary's class is for undergraduate and graduate students (graduate students do an additional research paper and presentation on a graphics-related topic) in the computer science degrees. The University offers undergraduate and graduate degrees in computer science and in computer information systems (CIS). This class, as many other computer graphics classes today, takes a CIS view of computers in business settings and applications, yet has the students learn how to use many graphics generation tools.

Computer Graphics Classes in General

Classes on computer graphics at high schools and community colleges usually emphasize how to make computer graphics, while 4-year and graduate programs tend to include or even focus on the theory of how computer graphics software programs work. Most of the computer graphics classes at the university level are offered from a computer science department and require a background in computer programming. University classes tend to include these topics in 2D and 3D graphics, as well as the mathematics behind some of these areas (Fedkiw 2015; Fussell et al. 2016; Schweitzer et al. 2010; Xiang and Plastock 2000):

- History of computer graphics
- Transformations
- Clipping
- Rasterizations
- Aliasing and anti-aliasing
- Projections
- Light, color, and shading
- Texturing
- Ray tracing
- Animation

Assignments in the classes range from mathematical problems within the graphics concepts to developing computer graphics products, usually from existing graphics tools. The tools most commonly used include OpenGL and the Adobe Creative Suite of tools such as Photoshop, Illustrator, and Flash.

The following example class includes many of these topics and shows how they might be organized in a class; however, the focus is on producing graphics for an overall purpose of branding and marketing an organization or person, culminating in the graphics products used with a website that students create.

Computer Graphics Class Example Details

The computer graphics class is often taught in a hybrid format where the class meets physically together four times in the semester. The first meeting is at the very start to do an overview, review assignments, and define the expectations of the class. Small assignments are due each week during the first month or so. In the middle of the semester, the students show some of their products to the class. The last two classes are toward the end of the semester and have graduate students present their research and everyone to show their final product, a website with all the previous products included in it. The rest of the presentations, tutorials, and materials are on the Blackboard course management system, separated into weekly sections of articles, presentations, and links to review.

The class covers the following topics and encourages that students learn the tools given that are part of the Adobe Creative Suite tools:

- History of computer graphics
- What a brand is
- Design principles
- Making graphics:
  - Two dimensional (Microsoft Paint, Adobe Photoshop/Gimp) transformations, clipping, and aliasing/anti-aliasing
  - Animation (Adobe Flash/Blender)
  - Web development (Adobe Dreamweaver/Weebly)
  - Three dimensional [optional graphic product] (Cinema 4D/Maya/3D Studio Max/Lightwave 3D) light, color, shading, texturing, and ray tracing

Beyond the assignments of sending an email each week with things like what brands to evaluate and what topic to research, the students turn in the following assignments that are typically worth between 100 and 200 points:

- Evaluate and write about three existing brands
- Create and write up their own brand about an organization or company
- Make a logo in MS Paint
- Develop a suite of logos (in a better tool)
- Post their brand idea and logo in a discussion
- Comment on each other's brand and logo
- Create, print, and present a business card, stationary, and a brochure about their brand
- Make an animation with their logo about their brand
- Create and present a website about their organization or company using the graphics that they have made
- Research and present a topic (100 points), for graduate students only

Students often do research in the following areas: anti-aliasing, computational geometry, finite element methods in graphics, fractals, graphics in virtual environments, modeling natural phenomena, modeling nonrigid objects, molecular graphics, morphing, particle systems, radiosity, ray tracing, rendering, shadows, surface and light interactions, texture mapping, turbulence, and visualization.

One of the assignments that makes this hybrid class unique and different is the posting of their

brand and putting a comment on every other student's brand and logo. In class, there would not be time for all students to make comments, and students might not make comments in the classroom.

Use Real Example Graphics

As part of the class, real graphics are shown that the professor made or had made for specific purposes. One of the main messages is to have a purpose for the graphics that are produced. For example, the International Space Development Conference of the National Space Society (www.NSS.org) in 1991 was chaired by the author. She worked with a graphic artist to develop an image that was used on posters, shirts, and brochures where the idea was to depict the Archimedes statement to give him a lever long enough and a place to stand and he could move the Earth. The conference theme was Space: A Call for Action. The conference was presented as the place to come find out about the actions large enough to get us moving and living off of the Earth. Figure 1 shows the resulting poster.

Many software development projects that included the development of graphics are presented such as an educational game called Dr Physio (Halff 2000) that taught middle school children better health behaviors including graphics for baboons, a lab, a savanna, basketball, food, scientists, a locker, a couch, exercise equipment, and a magazine. A recent example is from the San Antonio Ultimate Frisbee Leagues (SA Ultimate 2015) where a design is put on disks, bags, and shirts. That league is put on by a group of volunteers and the graphics are typically made by them. Figure 2 shows a design for a league from 2014 that had the theme of lost in space. The team names and colors were planets.

Student Example Graphics

Students have developed brands for all sorts of companies and organizations. Here are just a few of the ideas that they have developed:

- Book club
- Bookstore
- Brewing Beer
- Clothing sales
- Cloud services
- Coffee
- Computers
- Day care
- Family photos
- Flower shop
- Food:
  - Burgers
  - Dessert
  - Healthy
- Guard service
- Graphic design
- Help homeless
- Library
- Nuclear medicine
- Photography
- Resort
- Seaworld

Figure 3 shows many of the very creative business cards that have been developed by students that express their brand and include the logo that they made.

Teaching Computer Graphics by Application, Fig. 4 Handy Cloudware logos

As an example, one student developed a business he called Handy Cloudware. His name is Ken Handy, and he created a company to offer secure cloud solutions for businesses. His values were convenience, flexibility, simplicity, and safety. He first created the logos shown in Fig. 4, also showing the progression and improvement. Figure 5 shows a screen capture of his animation that showed the oval cloud spinning slowly between the hands. He used these graphics in his brochure and website for the company. He created some slogans and tag lines as well.

Conclusion

The students who have completed this computer graphics class are from many walks of life and many cultures especially from the United States, India, and Saudi Arabia. Students from various backgrounds and cultures can learn to make computer graphics in a meaningful way to express their values in a brand that they create.

Design review is an overachieving work of the urban planning process. Pattern of user interaction is largely dictated by the urban planning technology rather than diversity and creativity of the users. Traditionally, urban planning technologies include substantial use of paper-based plans, maps, and text documents. Currently, urban planners rely on digital technologies, which lack mobility.

Introduction

Design review work is conducted by a diverse group of agents who belong to different socio-economic-political institutions, where each agent

is a contributing entrepreneur in the ecology of the urban planning enterprise (Forester 1989). There is now a wide array of immobilized, single-user digital media that could support information and 3D visualization needs of the design review process (Bellotti and Bly 1996). However, mobility is fundamental for visual perception (Gibson 1986). Specifically, the design review process requires mobility that supports spontaneous interaction and participation, exchange of useful information, local communication, and mutual awareness. Technology for this process should support self-explanatory operations without significant training through mutual intelligibility of individuals and technological interactions (Suchman 2007; Norman 2010). Yet, these aspects of the design review process are not supported by exiting technology that is tied to desktop computers and afford explicit communication (Bellotti and Bly 1996; Luff and Heath 1998). There is, however, an absence of intelligent and intelligible 3D visualization media that allows participatory communication and ubiquitous, interactive behavior. Having such media could reduce the time needed to examine development proposals within the design review process. This media may also result in the preparation of development proposals that does not require knowledge of Computer Aided Design (CAD), Planning Support System (PSS), and Geographic Information System (GIS). Furthermore, the proliferation of interactive surfaces and their chameleon-like quality have pervaded both the public and work environments, and in education and entertainment, however, the role of representational affordances and properties provided by such surfaces within the design review process is still largely unexplored (Rogers and Lindley 2004; Murray 2012; Vishkaie 2014).

This entry aims to provide a comprehensive understanding of the role current and emerging technologies play in the design review process. It synthesizes a literature review of academic research that investigates the subjects of the design review process and its engagement in digital technology.

Technologies for Participation and 3D Visualization

Role of Technology in Urban Planning

Computers have evolved from expensive, fragile, remote, and hard-to-use devices to inexpensive, small, easy-to-use, fast, and more powerful microcomputers. Furthermore, visualization in CAD, PSS, and GIS has taken advantage of the development of fast, high resolution, and full-colored display computers. Moreover, practice of urban planning has become more accessible with significant improvement in the capacity and speed of data storage and communication devices from Local Area Networks (LANs) to the Internet. In addition, this trend introduced the paradigm of "virtual organization" that enables information to be available to urban planners independent of their geographically dispersed locations (Norman 1993, 2010; Bellotti and Bly 1996; Kock 1999; Vishkaie 2014).

In the past, without computers, urban planners previously worked with paper-based documents such as spreadsheets and sketches, as well as crafted material. However, urban planners optimistically began using computers for urban planning and design purposes in the 1960s. In that period, computer-assisted planning was used in professional practice for large-scale metropolitan land use and transportation models integrated with municipal information. Consequently, the failure of these models in the 1970s demonstrated that the rationale of science for urban planning in creating such models was mostly inappropriate for public participation. Nonetheless, the development of microcomputers in the 1980s and the availability of GIS in the 1990s reignited urban planners' optimism in using computer aided planning (Norman 1993, 2010; Bellotti and Bly 1996; Vishkaie 2014).

Fundamentally, however, urban planners continually fail to use computers to perform urban planning functions in their professional practice. This problem originates primarily from the limited understanding of urban planning technologies by urban planners, which is a result from failing to

consider the human element. Additionally, the underlying rational for the design of a new urban planning technology that supports the current attitude in urban planning practice is to understand the particular needs of urban planners. However, focusing on a particular technology or an expert system that requires extensive technical training limits the introduction of a new urban planning technology (Norman 1993, 2010; Bellotti and Bly 1996; Vishkaie 2014).

The concept of PSS (see PSS section, below) suggests that the combined use of a different range of information technologies and models can enhance the specific professional responsibilities of urban planning. An interactive style of computer manipulation has been made possible with the use of electronic spreadsheets, database management systems, and graphical-multitasking operating systems. But, computers in urban planning are mainly used for general-purpose tasks such as office functions, processing documents, monitoring budgets, and maintaining records, thus, failing to take full advantage of the benefits of technological tools (Bellotti and Bly 1996).

In urban planning, stakeholders normally find it difficult to understand and digest technical actions, such as quantitative analysis. A solution to this is more technological advancement in urban planning. Moreover, visualization is also a valuable source of information that could assist communicative interaction by providing more visual thinking and understandable representation. Ultimately, urban planning's fundamental premise is to develop an understanding of solving problems through communication and collaboration among many participants (Forester 1989; Bellotti and Bly 1996).

In the 1960s, urban planning as an applied science suggests the fundamental transition of urban planning perception from design, which focuses on the traditional design of the physical city to an applied science, which is concerned with social science theories and quantitative techniques. In addition, the applied science model of urban planning describes information as a value and a politically neutral resource. This perspective requires that urban planners should provide useful information that informs and improves the policy-making processes (Bellotti and Bly 1996).

In the 1970s, urban planning as politics describes that information in urban planning which is not straightforward. Computer-based information and analytic techniques were used then in urban planning to transmit information from inaccurate paper-based record to a more accurate and current digital form. As a result, this led to increased public awareness surrounding the urban planning process as previously obscured issues began to be revealed and became one of the most important political implications of urban planning computer-based information systems (Bellotti and Bly 1996).

In the 1980s, urban planning as a communicative action describes urban planning as a collection of information for improving the policy-making process. Urban planning also involves formulating policy, making plans and revisions, negotiating, explaining, interpreting legal status, and undertaking quantitative analysis (Bellotti and Bly 1996).

Today urban planning, as a collective and communicative design process, suggests that urban planners' computer-based tools and technologies must support collaborative urban planning and collective decision-making processes. Currently, social and ethical views on urban planning communication focus on lower levels of abstraction on decision-making processes. These views suggest "collective common sense" and "deciding and acting" within an "interactive and inter-subjective communication" that follows the knowledge and consciousness of individuals (Norman 1993, 2010; Bellotti and Bly 1996; Vishkaie 2014).

Furthermore, the evolution of information technology has been critical to the organization and analysis of data, and ultimately, the creation of knowledge. This can be viewed as an evolving concern in urban planning that data changes into different forms of information within systems such as Urban Information System (UIS) and Land Information System (LIS). Information can support knowledge-based systems, which focus on analytical modeling capabilities such as Spatial Decision Support System (SDSS) (Bellotti and Bly 1996; Vishkaie 2014).

In the following sections, examples of applications that address the issues of urban planning and design review are discussed. CommunityViz and

CityEngine are selected to introduce these commercial applications as they are occasionally used throughout the urban planning and design process. URP is also selected to introduce a tangible system created for academic research that also supports the urban planning and design process (Vishkaie 2014).

CommunityViz

CommunityViz is a modeling and scenario evaluation planning and decision support system with visual and interactive components for community planning and design. This software is based on Esri's ArcView GIS that integrates words, numbers, maps, diagrams, and images in an interactive real-time and multidimensional environment. Furthermore, this multiagent simulation system integrates 2D mapping information, 3D visualization, and policy simulation technologies. CommunityViz is an open-ended process that allows users to test and evaluate the implications of plans for communities and for viewing existing and proposed buildings simultaneously (Walker and Daniels 2011; Vishkaie 2014).

Moreover, CommunityViz is composed of a series of integrated modules. Scenario Constructor works as the spatial component within the ArcView two-dimensional GIS framework. TownBuilder 3D displays 2D data in a 3D virtual world and receive instantaneous visual feedback in real-time. Policy Simulator is a multiagent simulation module that is designed based on complexity theory. Urban planners and designers, members of community, and elected officials are the audience for CommunityViz (Walker and Daniels 2011).

CityEngine

Esri CityEngine is a 3D modeling software that uses GIS for geo-design based on 2D and 3D data. Furthermore, CityEngine is used for 3D city modeling in a virtual urban and architectural environment, simulation, game development, and film production. It also provides tools to generate and modify buildings, layout and edit street networks, distribute street furniture, create 3D road profiles, control the shape of the skyline, and analyze urban planning projects and aggregate geospatial data. Moreover, CityEngine has features for sharing 3D city scenes, editing tools, texturing façade, generating reports, visualizing 3D zoning rules, and integrating with ArcGIS. In addition, urban planners and designers and architects are the audience for CityEngine (Esri 2017).

URP: A Luminous-Tangible Workbench for Urban Planning and Design

URP is an urban planning and design and architectural system for a physically based workbench setting. It further explores for facilitation, manipulation, exploration, and discussion how several variables relate to physical objects. Furthermore, it employs several luminous-tangible interactions to present visual information related to physical architectural objects. URP also aims at facilitating the constraints of future urban design and considers the existing architectural structures. In particular, URP focuses on visualizing measures of distance, shadows, and reflections at different times of day, as well as wind flow around buildings. Moreover, URP tends to focus on providing fluid and easy-to-understand manipulations to facilitate computation and thus the concrete realization of an abstract concept of the building plan. Urban planners and designers are the audience for URP (Underkoffler and Ishii 1998).

CommunityViz, CityEngine, and URP Critique

However, CommunityViz, CityEngine, and URP are cumbersome systems to operate. While both CommunityViz and CityEngine are integrated with ArcGIS, working with such software requires knowledge of GIS, which conflicts with the skillsets of urban planners or the public.

Furthermore, the limited adaptability and availability of URP as physical architectural structures to various design scenarios are some of the shortcomings pertaining to this system. Moreover, due to the complexity of the CommunityViz, CityEngine, and URP, these systems are not commonly used during negotiations between urban planners and developers, nor between urban planners and the public. In contrast, these discussions rely on more conventional tools, such as pen and paper. To some degree, tools such as pen and paper support visual and spatial thinking and explication that would enhance collaborative and

collective decision-making during the negotiation and discussion phases of the design review process.

Yet, it remains unanswered under what circumstances systems like CommunityViz and CityEngine would work well for facilitating communication and to what extent a system like URP could be applied in the practical circumstances of urban planning. Furthermore, what subtleties or nuances in the goals of these urban planning activities impact the design requirements for such tools?

Planning Support System (PSS)

Planning Support System (PSS) is a decision support tool that facilitates the preparation and evaluation of plans. PSS attempts to promote collaborative communication and interaction amongst urban planning stakeholders. Further, it allows urban planning stakeholders to visualize their future cities, also to provide a better understanding of their decisions. Furthermore, PSS uses analytic tools and computer simulation models along with visual displays to focus on urban and regional economic, demographic analysis and forecasting, environmental modeling, transportation planning, predicting future development, and land use patterns (Bellotti and Bly 1996).

Moreover, PSS is also a multidimensional application based on complex attributes such as mathematical theories and theories focusing on the structure and behavior of urban entities, urban planning processes, and spatial representations. As an information framework, PSS also tends to provide an interactive, integrative, and participatory information infrastructure for urban planning procedures. On the contrary, GIS is a fundamental component of the PSS, which requires spatial thinking skills and knowledge of GIS, thus, complex and challenging features of PSS may contradict with the skillset of urban planning stakeholders. Thus, PSS does not offer the ultimate solution to urban planning problems, and it seems unlikely to replace conventional tools and technologies in urban planning. CommunityViz and METROPILUS are both examples of planning support systems (Bellotti and Bly 1996).

Urban Planning and Visualization

The urban planning process involves extensive visualization of 2D digital maps and 3D digital models. New digital technologies such as CAD, PSS, and GIS are becoming available to support the visualizations needs of the urban design and planning process. However, there is a gap in characterizing the primary concerns of urban planning stakeholders' software skills and functions that urban planning software provides (Bellotti and Bly 1996).

In particular, design review is an iterative process that begins by first understanding the problem context through data collection and analysis to find possible design solutions. The design review process further attempts to implement alternative plans within parallel design and decision activities, which converge through government mandate or profitable solutions. In most cases, design solutions are defined in a cyclic fashion, which depends on mobilizing the knowledge and expertise of several diverse professionals involved in the process of design review. Additionally, in the design review process, plans and various stages of design and decision-making require communication between experts, professionals, and the public. The end results of these communicative and participatory activities are plans that visualize aesthetics, economic, social, and functional issues (Bellotti and Bly 1996).

Furthermore, there is a complex connection between urban design and planning and the socio-economic-political institution that ultimately impacts the appearance of cities. Oftentimes, decisions that are made within socio-economic-political processes tend to address the consistency between land use, transportation, and air quality conflict with the analytical methods of urban design and planning. For example, transportation planning attempts to reduce congestion through a decrease in carbon dioxide (CO_2) emissions. Thus, to enhance the stakeholders' comprehension, the socio-economic-political implications of urban design and planning actions

should be accessible in visual formats (Bellotti and Bly 1996).

Specifically, the development of new digital technologies has moved visualization to be one of the most important activities in the urban planning and design process. For example, visualization technology for the urban planning and design process can help in problem-solving, evaluating plans, and presenting spatial information that informs analysis, prediction, and optimization. Recently, decision-making systems have been combined with Virtual Reality (VR), Cave Automatic Virtual Environment (CAVE), and holobench. These tools combine CAD, GIS, and multimedia or 3D GIS tools that include all of the functionality of 2D GIS. However, today, there is no evidence that CAVE is commonly being used by municipalities (Bellotti and Bly 1996).

Moreover, most of the current urban planning digital technologies focus on forward visualization that involves developing visual tools to support the public and interested groups. Yet, there are specific digital technologies developed for backward visualization that involves developing visual tools to support experts and professionals. However, absent is the presence of a visualization aid that specifically supports the value and significance of communication and participation in the design review process deliberation. As opposed to the current trend, such a visualization aid should avoid the separation of target users, depending on their level of expertise. Creating a balance between the needs of users would allow for integration of the workflow of urban planning stakeholders from naïve to expert, to address their challenges in a participatory manner (Bellotti and Bly 1996; Norman 2010).

Groupware and Computer-Supported Cooperative Work in Urban Planning

Urban planning has recently been involved with computer-supported techniques that try to maximize collaboration. These techniques include groupware, Computer-Supported Cooperative Work (CSCW), and cooperative and participatory design. Furthermore, "Groupware is an umbrella term for the technologies that support person-to-person collaboration; groupware can be anything from email to electronic meeting systems to workflow." Groupware also includes shared drawing, group decision support, and scheduling and project management. As well, groupware allows urban planning activities within groups to negotiate spatially while designing plans and sketches and writing documents (Laurini 2001).

In addition, to enhance work efficiency in the design review process, three important elements should be considered. First is agile communication and interaction, which aims at sharing information amongst urban planning stakeholders to negotiate possibilities and solve conflicts. Second is good information, which concentrates on cross-referencing submitted building proposals against bylaws and regulations. Third is effective processing and visualizing tools, which aim at providing spatial data handling tools and office automation functions (Jie et al. 2000).

Integration of these elements with groupware communication and interaction could be a useful mechanism to increase efficiency in the process of design review. For example, by having access to the Internet, groupware provides more opportunities for urban planning and design processes. This involves participation, increased productivity, fewer meetings, automating routine procedures, and the integration of geographically disparate teams. However, groupware involves limitations such as a lack of training and education for practitioners and the business community. The virtual workbench and virtual reality systems such as virtual cities are examples of a groupware setting (Laurini 2001).

Role of Interactive Surfaces in the Design Review Process

Digital media that would enhance visualization should be characterized by unpacking the ethical, communicative, and participatory challenges embedded within the socio-economic-political institution of the design review process. This issue should be characterized by the relationship between users from expert to naïve and technologies from old to new. Recognition of these challenges could lead to an attempt to reconcile

pluralistic values in the design of a new generation of a communication medium for the design review process using interactive digital media. There is a growing corpus of academic and industry work on this topic, however, there is a gap in the characterization of many aspects that would enhance the significance of visualization, communication, and equal participation in deliberation tied to the use of interactive surfaces (Forester 1987, 1989; O'Doherty and Einsiedel 2012; Vishkaie 2014).

Specifically, from a socio-technical point of view, the design review process is not adequately understood. In the design review process, technical and political conversations are media for making sense together. Communication throughout the design review process is a guiding instrument for back and forth and the iterative process of design. The design review process involves the participation of various individuals such as architects, developers, urban planners and politicians, who sketch, present, and modify ideas and concepts, also to review the paper and text-based bylaws and regulations. Furthermore, the design review process yet relies on the culture and use of traditional and somewhat inefficient tools and technologies (Forester 1987, 1989; Vishkaie 2014).

Examination of the design review process reveals that mobility is critical to the participatory work of urban planners. Mobility could possibly enhance tasks and responsibilities of urban planners. Local mobility that is a fundamental element to access individuals and shared resources is also essential to the design review process. Technology that supports local mobility would ease the informal and participatory interaction and awareness within the design review process. However, the requirements to support mobility in the participatory process of the design review have received little attention (Bellotti and Bly 1996; Scott et al. 2003).

In particular, "micro-mobility" refers to mobilizing and manipulating artifacts within the organizational setting, where various activities occur. Studying the design review process shows the "micro-mobility" of tools and technologies is critical to the work and communication amongst urban planning stakeholders. It is widely recognized that the access to real-time information, and the need for immediate collaboration with others, are essential parts of the design review process. However, the design review process still depends highly on the use of traditional paper and text-based documents (Luff and Heath 1998).

Exploring the design review process provides another lens of understanding about how the complexities of computer aided planning have not been featured in empirical studies of the communication and participation activities within the design review process. What has not been identified is that computer aided planning systems are currently bound to inflexible desktop workstations, whereas all urban planning stakeholders do not have access to the technological tools to participate in communication and design processes. In addition, typical single-user urban planning desktop computer applications do not support participatory and multiuser interactions required within the design review process (Luff and Heath 1998; Scott et al. 2003).

Moreover, participation that is a sensitive part of the socio-economic-political context of the design review process has been impacted by the traditional trend that has kept computer aided planning routinely at stationery workstations that have become increasingly complex. Group feedback has also been largely neglected by the limited movement of individuals who are still tied to complex and inflexible technologies. In exploring different stages of the design review process, the mobility of urban planning stakeholders, information, documents, and artifacts is considered fundamental in enhancing participation and communication (Luff and Heath 1998; Tufte and Mefalopulos 2009; Vishkaie 2014).

In the absence of a technology that provides a platform for generating a shared understanding through visualization, the manipulation of conversation occurs. As a result, urban planning stakeholders could interpret basic parameters differently. Thus, it can be argued that the process of participatory design and communication of the design review is significantly tied to the role of fixed technologies that are not easily accessible to all stakeholders. These fixed technologies are not

self-evident, thus they require a certain level of knowledge and expertise to perform urban planning work. Therefore, the prolonged process of the design review, a lack of knowledge of design and perspective, and insufficient comprehension are the results of inaccessible and inefficient exiting urban planning technologies, wherever the urban planning stakeholders attempt to participate and communicate (Forester 1987, 1989; Bellotti and Bly 1996; Vishkaie 2014).

The adaptation of fixed interactive surfaces to traditional desktop computers has recently become a concern to the research and industry communities. Such surfaces are becoming important tools for solving problems in urban planning. For example, the research community has explored that interactive surfaces are used for the planning and designing neighborhood (Fernquist 2010). The research community has also investigated the design of a collaborative PSS for use on a multitouch tabletop (Su 2011). Furthermore, an urban planning, nonimmersive virtual environment is designed for spatial analysis (Vandoren et al. 2005).

In addition, Mixed Reality (MR) that is used for a bimanual handheld urban planning interface supports searching, inserting, and creating contents (Sareika and Schmalstieg 2010). The Urban Sketcher is also designed to improve real-time communication amongst urban planning stakeholders (Sareika and Schmalstieg 2007). Further, augmented and mixed reality and interactive tangible tabletop and 3D printed models of buildings are used to improve participation in urban planning through the communication of digital models (Välkkynen et al. 2013). On a commercial level, CommunityViz, in combination with fixed interactive surfaces, provides regional information through the collective use of digital maps (Placeways 2017).

Discussion

Although this entry does not tend to propose an optimistic scenario of new media for the design review process, the cultural technologies of digital media imply user empowerment through enhancing individual liberty and social harmony. All of the arguments deemed above may further suggest directions for designing a mobile communications technology for the design review process to access geo-located and real-time information while on the move. This mobile communication technology could increase mobility and create a balanced communicative and participatory relationship between urban planning stakeholders by reaching a wide audience. The combination of mobile with fixed interactive surfaces would support the different forms of participation required for the design review process. This system should also have a limited amount of textual and diagrammatic documents, and instead have more graphical tools to clearly visualize ideas and concepts (Norman 1993, 2010; Murray 2012; Vishkaie 2014).

In a nutshell, traditional urban planning technologies highlight several shortcomings and challenges that require the consideration of complex accounts to be ameliorated. Although the use of interactive surfaces is not naïvely overrated, the purpose of this entry is to capture reflections on the complexities and challenges of thinking through improving visualization, communication, and participation as fundamental components of the design review process in the governance of new digital media genre (Norman 1993, 2010; Murray 2012; Vishkaie 2014).

Conclusion

Computer aided design, a planning support system, and a geographic information system are current technologies used in the urban planning process. Adaptation of interactive surfaces to the CAD, PSS, and GIS will be an avant-garde technological development in computer aided planning and other related fields. Previously, the affordances and properties of technologies that run on desktop computer applications have reduced draftsmen's needs for manual drafting and drawing. This then facilitated designers and engineers in pursuing their individual analytic, drafting, and drawing goals, although somewhat in isolation. Similar to the beginning of CAD creation, the adaptation of interactive surfaces to

CAD, PSS, and GIS is the next step in technological advancement, thus these developments will shorten the design cycle and lessen the associated design costs. To sum up, these changes foreshadow that an era of manual, somewhat inefficient, and inaccurate computation; 3D visualization vagueness; and interaction exclusively on single desktop interface metaphor is the way of the past. In the future generation of computer aided planning, and in a broader context of computer aided technology, knowledge and skill will not be the prerogative to experts and professionals. Instead, individuals with limited software skills will also be able to engage in the participatory design review process via the introduction of interactive communication media. Hence, the integration of interactive surfaces with easy-to-use technologies carries the potential to be in the forefront of the design a new genre of digital media for the design review process. In fact, this is the way of the future (Vishkaie 2014).

Considering these aspects, this entry shows how the study of technology within the design review process can provide rich insights into the individual and shared experiences that evolve around such digital media. These insights can guide the innovation and creation of user-centered designs for computer aided systems beyond limited capacities of the current CAD, PSS, and GIS (Vishkaie 2014).

Tensor Field Visualization

Tim McGraw
Purdue University, West Lafayette, IN, USA

Definition

A tensor, specifically a second order tensor, is a linear mapping from vectors to vectors and is represented by a multidimensional array of values called its "components."

A tensor field is a mapping from each point in some spatial domain (usually 2D or 3D) to a tensor.

Tensor field visualization is the process of visually representing tensor fields so that features of interest in the field become apparent to the viewer.

Introduction

Some physical phenomena can be represented by a single number, or *scalar* value. Temperature and density are well-known examples. Other quantities characterized by a magnitude and direction, like force and velocity, are represented as a *vector*. Yet other phenomena, like mechanical stress and diffusion, are represented by a *matrix*. This progression, from scalar to vector to matrix, is generalized by the concept of tensor order. Tensors of order 0 are represented by scalars, tensors of order 1 are represented by vectors, and tensors of order 2 are represented by matrices. The order of a tensor can be thought of as the number of indices required to uniquely identify the components of the tensor. In d dimensions a tensor of order n has d^n components. Using subscript notation a second-order tensor is written as $\boldsymbol{D}_{ij}$ where each of the indices, i and j, can have d possible values.

In general, tensors may have two different types of indices, covariant and contravariant. These are differentiated by using subscripts for covariant indices and superscripts for contravariant indices. For tensors in Euclidean space (i.e., Cartesian tensors) the two types of indices are equivalent, so only subscripts are used. In this work we concentrate on Cartesian tensors in 3D ($d = 3$).

A *tensor field,* $\boldsymbol{D}(\boldsymbol{p})$, is a mapping which assigns a tensor, $\boldsymbol{D}$ to each point, $\boldsymbol{p}$, in a spatial domain. Analogously we can define *scalar fields* as mappings from points to scalar values, and *vector fields* as mappings from points to vectors.

Second-order tensors are often analyzed and described in terms of the properties of the matrices that represent them. Symmetry implies that the tensor does not change when the order of indices

is changed, $\boldsymbol{D}_{ij} = \boldsymbol{D}_{ji}$. In 3D ($d = 3$) the symmetric second-order tensor,

$$\boldsymbol{D} = \begin{bmatrix} D_{xx} D_{xy} D_{xz} \\ D_{xy} D_{yy} D_{yz} \\ D_{xz} D_{yx} D_{zz} \end{bmatrix} \quad (1)$$

has six unique components: D_{xx}, D_{xy}, D_{xz}, D_{yy}, D_{yz}, D_{zz}.

The eigenvalues and eigenvectors of a matrix are defined by the relation

$$\boldsymbol{D}\mathbf{v} = \lambda \mathbf{v}. \quad (2)$$

The scalar values, λ, and vectors, $\mathbf{v}$, that satisfy this relation are called the eigenvalues and eigenvectors, respectively, of the matrix $\boldsymbol{D}$. It is difficult to give a general intuition for the meaning behind the eigenvalues and eigenvectors of a matrix, but they provide a simplified representation of the linear transformation represented by a matrix. For some special cases of matrices, there are known properties of eigenvalues and eigenvectors.

- Real-valued symmetric matrices have mutually orthogonal eigenvectors and real-valued eigenvalues.
- Positive-definite matrices (such that $\boldsymbol{x}^T \boldsymbol{D}\boldsymbol{x} > 0$ for all $\boldsymbol{x}$) have positive eigenvalues.

It is common to sort the eigenvalues from largest to smallest absolute value, and index the eigenvalues and corresponding eigenvector by this sorted order such that $|\lambda_1| \geq |\lambda_2| \geq ... |\lambda_d|$. In this notation the eigenvector corresponding to λ_i is $\mathbf{v}_i$.

Applications

In engineering and science, most tensor field visualization applications involve symmetric second-order tensors, which are the main focus of this work. Some physical processes which involve tensor quantities are molecular diffusion in liquids, which has implications in medical imaging, and mechanical stress and strain. In mathematics, tensors are used to describe the differential geometry of manifolds. Asymmetric tensors arise when the gradient of a vector field is computed. For example, the gradient of a velocity field is used in the study of fluid mechanics, and the gradient of a deformation field is useful in solid mechanics analyses.

Diffusion

Brownian motion is the random molecular motion which leads to water transport at a microscopic scale within living organisms. The structure of the surrounding tissue can influence the diffusion process, sometimes making it directionally dependent (or *anisotropic*). In Gaussian diffusion, the directional dependence is characterized by a symmetric, positive-definite second-order tensor known as the "diffusion tensor." It can be computed in terms of the covariance matrix of the normal distribution which describes molecular displacement probabilities.

Within an oriented structure, such as the white matter of the brain which consists of bundles of parallel neuronal fibers, the principal diffusion direction (PDD) tends to be parallel to the fiber direction. Magnetic resonance imaging (MRI) protocols have been developed which permit the diffusion tensor to be estimated. The diffusion tensor can be used to infer tissue structure at the millimeter scale and describe the directional dependence of diffusion. The PDD is given by the eigenvector $\mathbf{v}_1$ of the diffusion tensor.

In the 1990s, diffusion tensor MRI (DT-MRI) (Basser et al. 1994) enabled white matter structure to be indirectly assessed by estimating the attenuation of the MRI signal due to diffusion of water molecules. More recently, the imaging technique has been refined using more general models of the diffusion process, including non-Gaussian diffusion characterized by tensors with order greater than 2. This has resulted in improved fiber tractography techniques and enabled more precise assessment of anatomical connectivity in the brain. Visualizing tensor fields in this context can lead to improved understanding of brain architecture and permit clinicians to make diagnoses on the basis of DT-MRI.

Stress and Strain

When external forces are applied to a material, internal stresses are produced which lead to deformation, also known as strain. The second-order strain tensor $\boldsymbol{\epsilon}_{ij}$ represents the changes in shape of a material under stress. The second-order stress tensor, $\boldsymbol{\sigma}_{ij}$, provides a complete description of stress at a point. Given an axis-aligned infinitesimal cube, the index i represents force components, and index j represents the components of the normal to the surface on which the force acts. So, for example, the component $\boldsymbol{\sigma}_{xy}$ is the force in the +x-direction acting on the +y-face of the cube. Conservation of angular momentum dictates that the stress tensor is symmetric. Unlike the diffusion tensor, the stress tensor is not necessarily positive definite. It may have negative eigenvalues, such as when compressive external forces are applied to a solid. Visualization of stress tensors can assist engineers in the design and analysis of structures.

Glyphs

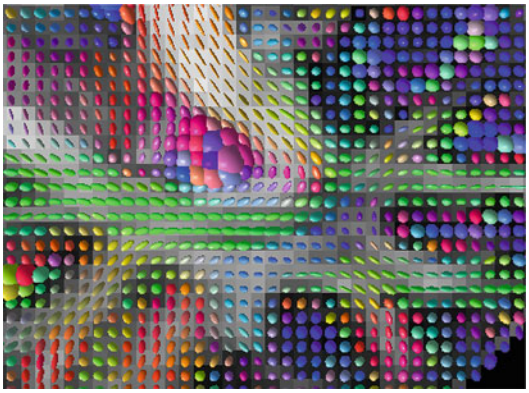
Glyph-based visualization techniques display a small graphical icon at each point in a domain to represent a tensor. One of the most commonly used tensor glyphs is an **ellipsoid** computed by transforming the 3D vertices, $\mathbf{p}$, of a triangulated sphere by the tensor, $\boldsymbol{D}$ yielding transformed vertices

$$\mathbf{q} = \boldsymbol{D}\mathbf{p}. \tag{3}$$

Ellipsoids for the tensors

$$\boldsymbol{D}_1 = \begin{bmatrix} 3\,0\,0 \\ 0\,1\,0 \\ 0\,0\,1 \end{bmatrix}, \boldsymbol{D}_2 = \begin{bmatrix} 2\,-1\,0 \\ -1\,2\,0 \\ 0\,0\,1 \end{bmatrix}, \boldsymbol{D}_3 = \begin{bmatrix} 1\,0\,0 \\ 0\,1\,0 \\ 0\,0\,1 \end{bmatrix} \tag{4}$$

are shown in Fig. 1.



Tensor Field Visualization, Fig. 2 Detail of ellipsoidal glyphs computed from DT-MRI of the human brain

This glyph gives a visual representation of the tensor that can be understood in terms of the eigenvalues and eigenvectors of the tensor without requiring them to be explicitly computed. The major and minor radii of the ellipse are given by the eigenvalues of the tensor. The major axis of the ellipse is given by the eigenvector corresponding to the maximum eigenvalue of the tensor, λ_1. In diffusion applications the major axis is known as the principal diffusion direction (PDD), the direction in which diffusivity is highest. Diffusion ellipsoids for a slice of DT-MRI data are shown in Fig. 2. For a stress tensor the major axis of the ellipse corresponds to the major principal stress axis.

For symmetric tensors in 3D there are three characteristic ellipsoid glyph shapes that emerge, depending on the relative magnitudes of the three eigenvalues.

- Linear "cigar" shapes elongated along one direction, $\lambda_1 \gg \lambda_2 \approx \lambda_3$
- Planar "pancake" shapes flattened along one direction, $\lambda_1 \approx \lambda_2 \gg \lambda_3$
- Spherical shapes, $\lambda_1 \approx \lambda_2 \approx \lambda_3$ which represent isotropic phenomena

Another type of tensor glyph, the **Reynolds glyph,** is computed in terms of the spherical coordinates (r, θ, ϕ) of each point, **p,** on a sphere. The glyph is created by setting the radial coordinate of each point to

$$r = \mathbf{p}^T \boldsymbol{D}\mathbf{p}, \tag{5}$$

where $\mathbf{p}^T$ is the transpose of **p**. The result is a peanut shaped glyph which is elongated in the direction of the major eigenvector. For positive-definite (PD) tensors (tensors with all eigenvalues being positive) all r values of the metric glyph will be positive. For tensors which are not PD the sign of r is usually mapped to color to give a visual indicator of the sign of r. In stress tensor visualization, this help differentiate states of tension and compression. Reynolds glyphs for the tensors in Eq. 4 are shown in Fig. 3.

The appearance of ellipsoid and Reynolds glyphs can be uninformative from some viewpoints. For example, it can be difficult to differentiate between a cigar-shaped ellipsoid and a pancake-shaped ellipsoid viewed edge-on. Superquadric glyphs (Kindlmann 2004) were proposed to overcome this visual ambiguity. Superquadric shapes can include ellipsoids and other shapes, such as cylinders and cuboids. Superquadric glyphs corresponding to the tensors in Eq. 4 are shown in Fig. 4.

Westin et al. (2002) developed a composite glyph to mitigate the problem of visual ambiguity. Their solution was a glyph which combined independent visualizations of linear, planar, and spherical shapes.

Cauchy stress glyphs, or quadric glyphs, are defined as the implicit surface

$$\boldsymbol{p}^T \boldsymbol{D}\boldsymbol{p} = \pm k^2. \tag{6}$$

These glyphs are useful for examining the case of pure shear in a solid.

Particle systems are a discrete approach to visually representing a tensor field using animation. Each particle is an icon or glyph representing a tensor which moves along the $\mathbf{v}_1$ field. The particle appearance changes as it moves to reflect the tensor at the current position. A GPU implementation was described by Kondratieva et al. (2005) to accelerate particle rendering and animation in the context of DT-MRI visualization.

Glyph based techniques are prone to some well-known problems. When applied to large datasets, the display can become too cluttered to be useful. In 3D datasets, the glyphs can occlude each other. The local structure that they convey can depend on viewpoint and at times become totally impossible to discern.

Glyph Placement

A naive approach to visualizing a tensor field is to simply place a glyph at each measured data location. However, whether the measured data are irregularly spaced or on a grid, this glyph

Tensor Field Visualization, Fig. 3 Reynolds glyphs

Tensor Field Visualization, Fig. 4 Superquadric glyphs

placement can give misleading results. Data points too far apart can make interpreting the field between points difficult. Dense data points can result in many glyphs which obscure each other. The pattern of datapoint locations, such as on a regular grid, can lead to visual artifacts which mask actual features in the dataset. It is difficult to elaborate an optimal strategy for glyph placement since it may be dependent on the specific dataset and the task at hand.

Kindlmann and Westin (2006) presented a strategy for placing tensor glyphs which emphasizes the coherent structures of DT-MRI that emerge along fiber tracts. They define attraction and repulsion forces between glyphs that move them into a packed arrangement such that overlaps are minimized and coherence along tracts is emphasized. However, placing tensor glyphs between datapoints raises the question of how to interpolate tensors.

Tensor Lines and Surfaces

Streamlines (or integral curves) are curves which are locally parallel to a vector field at every point along the curve. Streamtubes have a circular cross section and their axis is a streamline. Although streamlines and streamtubes are usually vector field visualization techniques, they can be adapted to reflect tensor field information by considering the vector field of v_1, the major eigenvector of each tensor in the field.

Soon after the development of DT-MRI, tractography (the process of tracing white matter pathways in the brain) was developed (Basser et al. 2000). Early approaches to tractography were inspired by streamline tracing techniques. By repeatedly stepping in the principal diffusion direction, white matter fiber tracts can be reconstructed. Tracts visualized as streamtubes are shown in Fig. 5. However, in DT-MRI tractography becomes unreliable in regions where anisotropy becomes low, so additional tensor information must be used to prevent meaningless streamlines from being created. With the second-order tensor model of diffusion, anisotropy may become low due to the absence of white matter or due to crossing or branching fibers.

"Hyperstreamlines" (Delmarcelle and Hesselink 1993) include additional information about the tensor field by generalizing the streamtube cross section from a circular shape to an ellipse. The geometry of that ellipse is defined by the other eigenvectors ($\mathbf{v}_2$ and $\mathbf{v}_3$) and eigenvalues (λ_2 and λ_3) of the tensor at each point.

Streamsurfaces forming continuous surfaces in regions where the diffusion ellipsoids have a flattened "pancake" shape have also been proposed to visualize tensor fields.

As with solving the problem of glyph placement, interpolation becomes a problem in streamline and streamsurface generation since we generally wish for the curves and surfaces to have a smooth high-resolution appearance with respect to the set of data points. Approaches to tensor field interpolation include linear interpolation of tensor components, log-Euclidean interpolation, and polynomial functions with physical constraints.

Tensor Invariants

Tensor invariants are scalar values computed from the tensor which are invariant under changes of

coordinate system. The eigenvalues of the tensor are invariants, and therefore many other invariants can be expressed in terms of the eigenvalues. A tensor field can be converted into multiple scalar fields of invariants which can then be visualized using scalar field visualization techniques, such as volume rendering, or the scalar invariants can be incorporated into other tensor field visualizations, such as determining the color of streamlines or glyphs.

Fractional anisotropy (FA) can be computed as the normalized variance of the eigenvalues,

$$FA = \sqrt{\frac{3}{2}} \times \frac{\sqrt{(\lambda_1 - \overline{\lambda})^2 + (\lambda_2 - \overline{\lambda})^2 + (\lambda_3 - \overline{\lambda})^2}}{\sqrt{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}}, \tag{7}$$

where $\overline{\lambda}$ is the average of the three eigenvalues. FA has found much clinical success in assessing, for example, brain trauma, multiple sclerosis lesions, and stroke in DT-MRI. Geometrically, FA represents the elongation or eccentricity of the ellipsoidal glyph of a tensor. In diffusion tensor imaging, high FA values are associated with the presence of white matter fibers. Color FA images can be generated by combining intensity information from the FA image with color information computed from the PDD by $(r, g, b) = (|PDD_x|, |PDD_y|, |PDD_z|)$ as shown in Fig. 6.

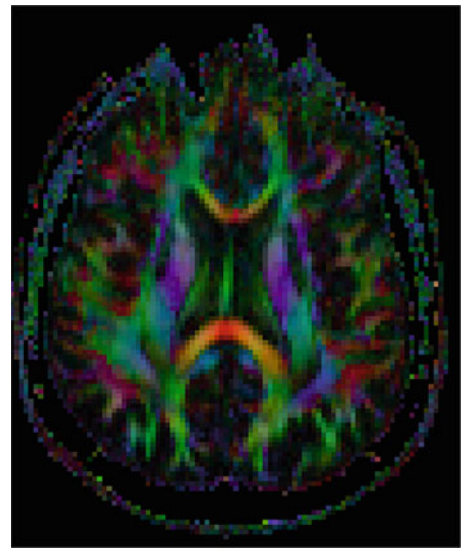
The shape of the ellipsoid glyph can be seen as a combination of linear, planar, and spherical elements, each of which can be quantified by the following measures: the linear shape index

$$CL = \frac{\lambda_1 - \lambda_2}{3\overline{\lambda}} \tag{8}$$

the planar shape index

$$CP = \frac{2(\lambda_2 - \lambda_3)}{3\overline{\lambda}}, \tag{9}$$

and the spherical shape index



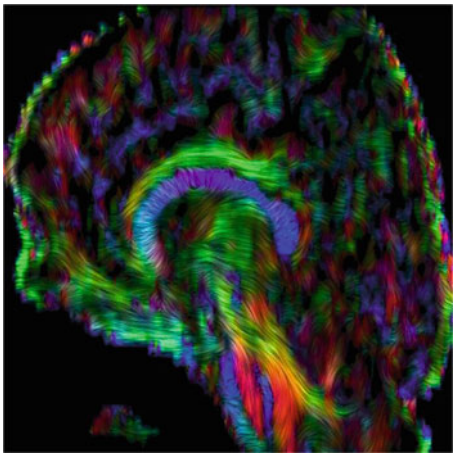
Tensor Field Visualization, Fig. 6 Color FA visualization of DT-MRI. Axial view of human brain

$$CS = \frac{\lambda_3}{\overline{\lambda}}. \tag{10}$$

These indices can be used to form composite glyphs, or to switch between visualization methods, such as using hyperstreamlines where *CL* is high, and glyphs elsewhere.

Texture-Based Approaches

Texture-based tensor field visualization methods create an image in which texture frequency and orientation represent the tensor field. Line integral convolution (LIC), introduced by Cabral and Leedom (1993), creates an image with slowly varying intensities along each streamline, and rapidly varying intensity perpendicular to streamlines. An LIC image is generated by blurring a noise image with a curvilinear kernel aligned with the streamline passing through each voxel. Hsu (2001) first explored the use of LIC on tensor fields to create DT-MRI images of cardiac muscle fibers in the human heart. McGraw et al. (2002) extended this technique by fusing the LIC texture and the color FA image to produce a visualization depicting diffusion direction and anisotropy, as shown in Fig. 7. Zheng and Pang developed "HyperLIC" (Zheng and Pang 2003), a technique which allows all three eigenvectors of the 3D



Tensor Field Visualization, Fig. 7 Line integral convolution visualization of DT-MRI. Sagittal view of human brain

tensor to contribute to the texture. Laidlaw et al. (1998) proposed a hybrid visualization approach using texture-mapped glyphs. The patterns on the resulting glyphs can portray all six unique symmetric diffusion tensor components (see Eq. 1). By overlaying the glyphs on a scalar image, such as FA, a layered image can be created.

Topological Approaches

Topological approaches to vector and tensor field visualization reduce the field to a sparse set of feature points and curves. Previous approaches to topological tensor field visualization defined degenerate points as locations where two or more eigenvalues are equal to each other. The topological skeleton of the tensor field can be defined as the set of degenerate points and the hyperstreamlines which connect them. The hyperstreamlines partition the tensor field into regions of homogeneous behavior.

Zheng et al. (Zheng and Pang 2004) described several categories of feature points and provided numerically stable methods for extracting them. The points were then connected to form feature lines. By using discriminant analysis, they were able to locate critical features with subvoxel accuracy. Several topological approaches specific to DT-MRI have been based on scalar field topology. Topological structures in scalar fields can be defined in terms of ridges, valleys, or crease lines. To apply these methods to DT-MRI, the scalar fields formed by tensor invariants are often considered. Tricoche et al. (2008) investigated tensor mode (eigenvalue skewness), and Kindlmann et al. (2007) considered fractional anisotropy (eigenvalue variance). Schultz et al. (2007) presented another approach using degenerate lines computed from probabilistic tractography. They also describe a robust method for computing crease surfaces from tensor fields.

Higher-Order Tensors

Visualizing fields of tensors of order greater than two has been a less active research area. Most of the proposed visualization approaches use glyphs. A limitation of the second-order tensor model of diffusion can be observed from the shape of its glyphs – multiple peaks cannot be represented. In terms of DT-MRI that means that when two fiber pathways intersect, the resulting ellipsoid looks like a "pancake," not a shape with two independent peaks. High-order tensors have been used to describe non-Gaussian diffusion by Ozarslan et al. (Özarslan and Mareci 2003). Diffusion within the brain can be non-Gaussian, for example, where white matter fibers bifurcate or intersect.

Due to the fact that diffusion is antipodally symmetric (equal in opposite directions), only even order tensors are valid diffusion representations. Fourth, sixth, and eighth order tensors have been proposed as models for diffusion.

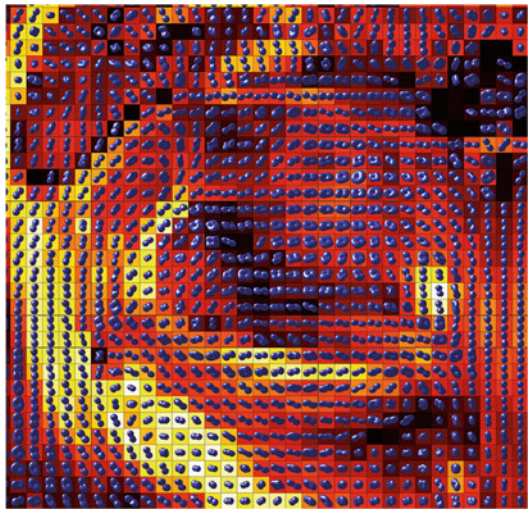
The second-order tensor Reynolds glyph described in Eq. 5 can be rewritten in tensor subscript notation as

$$r = \sum_i \sum_j \boldsymbol{p}_i \boldsymbol{p}_j \boldsymbol{D}_{ij}, \tag{11}$$

and this equation can be extended to fourth-order tensors as

$$r = \sum_i \sum_j \sum_k \sum_l \boldsymbol{p}_i \boldsymbol{p}_j \boldsymbol{p}_k \boldsymbol{p}_l \boldsymbol{D}_{ijkl}. \tag{12}$$

The resulting fourth-order tensor glyph will display peaks aligned with one or two fiber



Tensor Field Visualization, Fig. 8 Fourth order tensor Reynolds glyphs overlaid on a heat map of generalized anisotropy

directions. A higher-order tensor model is required in order to resolve more crossing fibers. An example of a 4th order tensor field visualized with Reynolds glyphs is shown in Fig. 8.

In solid mechanics, the fourth-order stiffness tensor, $\boldsymbol{C}_{ijkl}$, relates mechanical stress to strain by the generalized Hooke's Law,

$$\boldsymbol{\sigma}_{ij} = \sum_k \sum_l \boldsymbol{C}_{ijkl} \boldsymbol{\epsilon}_{kl}, \qquad (13)$$

where $\boldsymbol{\sigma}_{ij}$ is the second-order stress tensor and $\boldsymbol{\epsilon}_{kl}$ is the second-order strain tensor. Analysis and visualization of the stiffness tensor is important to understanding engineering failures due to fracture.

Tensorlines can be generated from higher-order tensors, but extracting the correct direction is confounded by several issues. First, we cannot simply compute eigenvalues and eigenvectors of a higher-order tensor – a more involved optimization scheme must be used to determine the directions of the peaks. Secondly, in high-order DT-MRI, the peaks in diffusivity no longer correspond to the underlying fiber directions. However, it is possible to efficiently compute a fiber orientation distribution (FOD) tensor (Weldeselassie et al. 2012) which represents the directions of the white matter fibers.

Scalar invariants computed from higher-order tensors, including a generalization of FA to high-order tensors (called "generalized anisotropy"), were presented by Ozarslan et al. (2005).

Definitions

Single-Player Game	A game that is designed for single-player mode where only one player is expected throughout the entire gameplay.
Role-Playing Game	A game that each player assumes a particular role in the gameplay.
Action Adventure Game	A game that combines core elements from both action game and adventure game genres

Introduction

The Elder Scrolls V Skyrim is a single-player role-playing RPG game. Bethesda game studios developed Skyrim and published it through Bethesda Softworks. Released in 2011 for PlayStation 3 and Xbox 360, this game has gone on to win numerous awards and more than 200 Game of the Year awards. Skyrim is an open-world game that allows the player to explore the world of Tamriel. Players can explore dungeons, complete quests, and craft new weapons and equipment (Hodgson et al. 2012; Elder Scrolls 2022).

Gameplay

The Elder Scrolls V Skyrim is primarily a first-person RPG game (with an optional third-person

view) that utilizes diverse fighting styles. Players can use one-handed weapons such as swords and maces or two-handed weapons such as war hammers and axes. Players can also use magic spells such as fire and ice to combat enemies. Other aspects of gameplay include archery, which allows the players to fight enemies with bows and other ranged weapons such as a crossbow.

DLC

Skyrim includes three DLCs. These DLCs contain new areas and side quests for the character to complete. The expansions include Dragonborn, Dawnguard, and Hearthfire. The Dragonborn DLC introduces new areas to the player, such as the island of Solstheim. On this island, the players venture on a quest to stop the false Dragonborn Miraak. The island offers new areas to explore, weapons and armor, and creatures and plants. Dawnguard introduces Vampires into the world of Skyrim. This DLC allows players to befriend and join the vampires or join the Dawnguard and fight the vampires. The vampires will take you on a variety of quests with the end goal of helping the vampires block out the sun. While the other two expansions offer plenty of updated content, Hearthfire is a much smaller DLC. Hearthfire allows the player to construct their own home within Skyrim. Players can customize their homes to their liking and decorate them any way they choose.

Plotline

The main story focuses on the player's character, the Dragonborn, which can talk and communicate with dragons via dragon shouts. The main quest line of Skyrim presents the player with the task of stopping the evil dragon Aulduwin who threatens to consume all of the mortal world. It is up to the Dragonborn to save the continent of Tamriel from certain doom. The main quest line is a wonderful place to start within the massive world of Skyrim to gain levels quicker and unlock more skills.

Character Creation

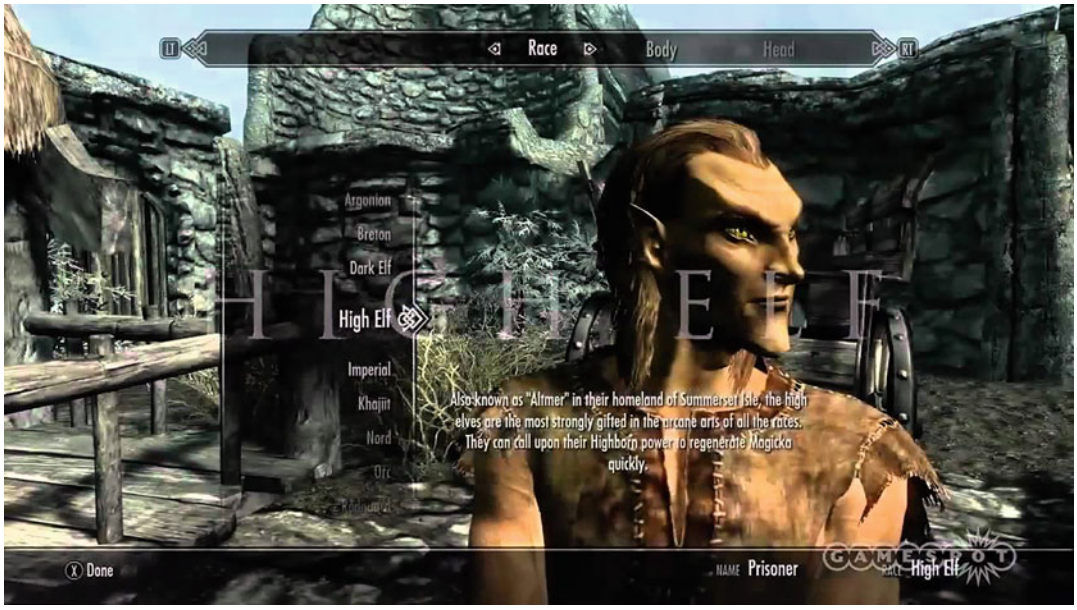
Skyrim allows the player to customize their character by choosing a variety of races in the world. Each race has a unique race ability that other races in Skyrim do not have (see Fig. 1). For example, some of the races in Skyrim include Argonians. These lizard-type creatures have a unique ability to hold their breath underwater for extended periods. Other races include the Nords, High Elves, Khajiit, and Wood Elves. The High Elves have bonuses to magical spells, and the Khajiit have increased thief skills such as improved stealth and pickpocketing. Nords are the humans in Skyrim, and they have increased resistance to the cold and are naturally better with swords and hammers. Wood Elves have increased benefits from archery. Several other Skyrim races are worth checking out, such as the Redguard and the Orcs.

Skill Trees

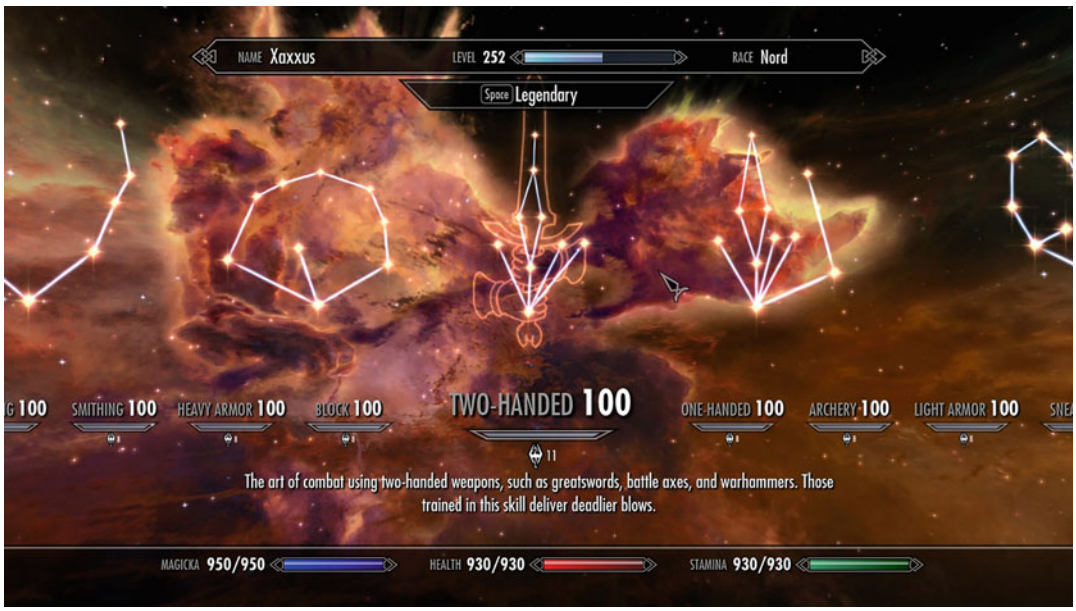
Skyrim provides players with a unique leveling system that is primarily skill-based. Each time you level up, the player gains skill points. The character can use these skill points to level the various skill trees in the game. The skill trees consist of three main sections. These include the mage, warrior, and thief trees (see Fig. 2). The mage class tree contains improvements to various spell classes, such as destruction and alteration. The warrior section focuses on improving one-handed or two-handed skills with weapons. Finally, the thief tree includes enhancing the ability of stealth, lock picking, and pickpocketing.

Dragon Shouts

As a Dragonborn, the player can cast what is known as dragon shouts (Maher 2022). These are magical abilities that are cast from the character's mouth. These shouts range from summoning dragons to throwing enemies backward. Characters can learn a dragon shout by learning the



The Elder Scrolls V Skyrim, Fig. 1 Skyrim Character creation screen: High Elf



The Elder Scrolls V Skyrim, Fig. 2 Skyrim Warrior Perk Tree

words of the shout. Shout words unlock by finding word walls. Word walls contain the words of ancient shouts. The player discovers word walls by exploring the Skyrim terrain. Once the player discovers a shout, the player can unlock more ancient dragon words to harness the full potential of a shout. Harvesting dragon souls of slayed dragons unlock these ancient words.

Holds

The world of Skyrim splits into various regions. Each of these regions has a significant hold or city. Holds are considered the major administrative sections of Skyrim. There are nine essential holds scattered across the landscape of Skyrim. Some of the major cities in Skyrim are Whiterun, Riften, Markarth, and Solitude (the capital city). These cities offer the player various shops to buy weapons and armor. Other shops also allow the player to purchase potions and enchantments with in-game gold that can improve the player's weapons and armor. The cities of Skyrim are also an excellent place for players to find side quests or jobs to complete.

Mods

One of the unique things about Skyrim is its large community of modders and creators. Modding a game allows the player to add new things to the game. For example, there is a mod to spawn chickens that would explode when shot with a bow and arrow. The Skyrim modding community has helped keep Skyrim thriving by adding mods that completely overhaul the game experience. There are over 70,000 available mods for Skyrim that players on the PC platform can experience completely free of charge. In addition, the newer generations of consoles have also opened support for mods. As a result, mod support has allowed console players to experience a wide range of mods and community-made content.

Reception

Since the release of Elder Scrolls V Skyrim in 2011, the game has sold over 30,000,000 copies worldwide. Skyrim has been Bethesda game studios' most successful game ever. Even their other popular titles, such as Fallout, have not surpassed this number in sales. In addition, Skyrim has survived three generations of consoles, releasing on the Xbox 360 and PlayStation 3, Xbox One and PlayStation 4, and more recently the PlayStation 5 and Xbox's Series X console.

Conclusion

There are many ways that players can approach the world of Skyrim. It offers players a variety of classes and characters, allowing them to explore the world with their preferred playstyle. The ability for the player to adapt various playstyles keeps Skyrim fresh and engaging for years. As a result, Skyrim has become one of the best-selling games of all time, having sold over 30,000,000 copies within a decade (Edwards 2021).

The New Age of Procedural Texturing

Definition

In the computer graphics and game development worlds, a *texture* is the digital representation of the appearance of a surface; *procedural texturing* is the process of using an algorithm in order to generate a texture.

Introduction

We believe we have entered a new age for procedural texturing, an age where these techniques are not only interesting to the theoretically concerned, the technically minded 3D artists who put them into practical use, but to a wider audience. Procedural techniques have indeed now extended past the most high-end of game development studios and the VFX and animation houses that gave them their first homes. As this new age progresses, the presence and use of procedural techniques for creating textures are only going to grow more entrenched in the years to come.

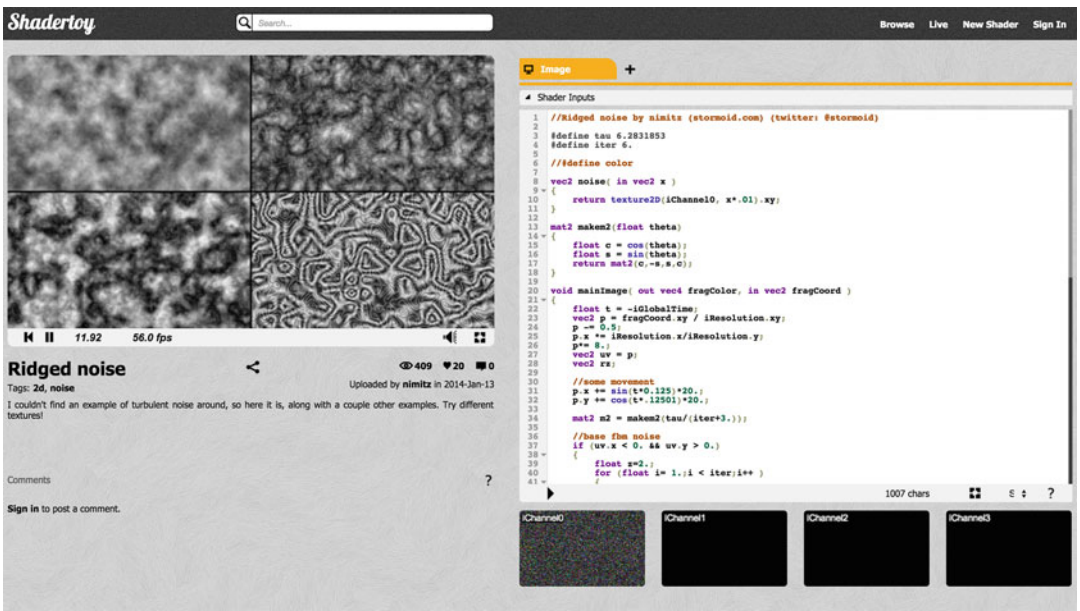
In this entry, we will focus mainly on the reasons why this new age is upon us and on some of the new techniques and approaches that have emerged in the past few years. The subject of procedural texturing, in itself, is already very known and covered (see in particular Ebert et al. 1998 for more on this topic), so we will not go into much detail about the science behind procedural texturing; rather, we'll focus on the exploration of new trends emerging from the visual effect and gaming industries.

What Is a Procedural Texture?

A procedural texture is a computer-generated image created using an algorithm (this is where the term *procedural* is derived from: a *procedure* is driving the process), instead of a digital painting or image processing application such as Adobe™ Photoshop™ (see Figs. 1 and 2).

Procedural texturing involves a two-step process:

- **The "authoring" phase**: During this first phase, procedural texture authors pick and combine the techniques they want to use, set the parameter values that drive these techniques, and expose the meaningful parameters



The New Age of Procedural Texturing, Fig. 1 The four textures on the *left* have been procedurally generated using four different parameter values from the procedure code on the right (Extract from Inigo Quilez's online tool Shadertoy Beta; see Quilez n.d.)

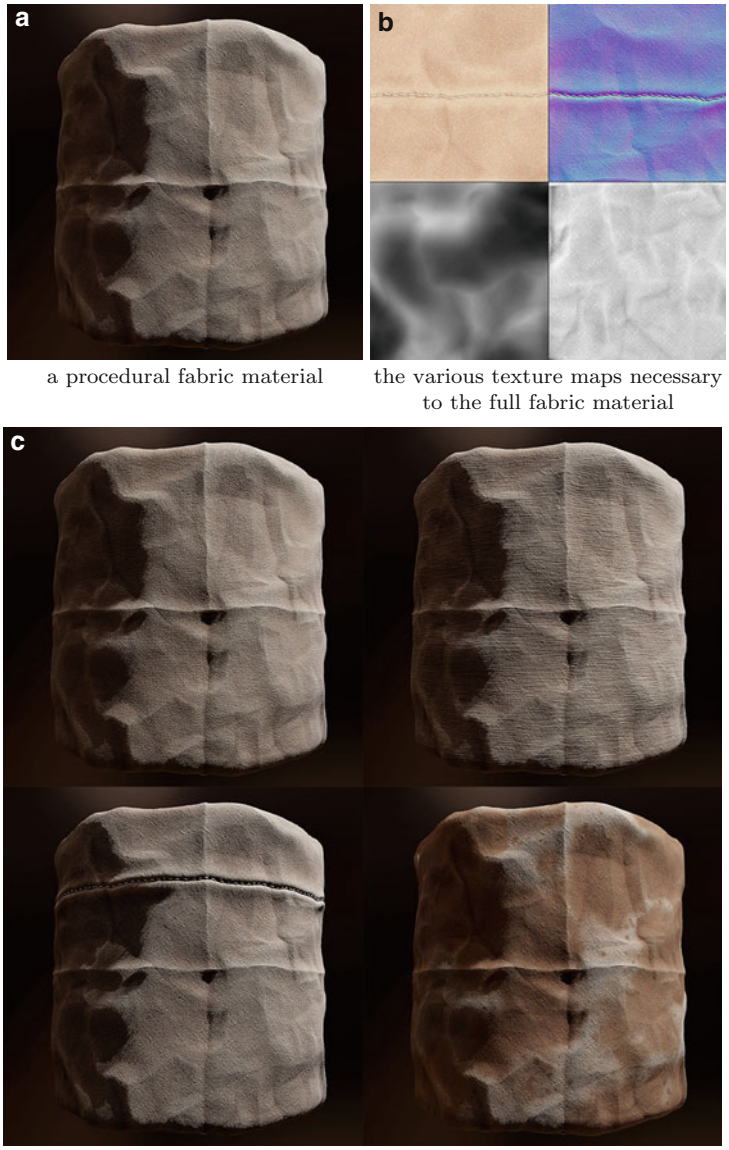
allowing to change the resulting textures' look and feel (see Fig. 3). These parameters can be of any type, from numerical values (the fractal dimension of a fractional Brownian motion generation algorithm, for instance; see Sébastien et al. 2000) to complex multi-array data (an image, i.e., an array of RGB numerical values, can in that respect be treated as a parameter to procedural texturing algorithms; see Fig. 4). At this authoring stage, the result of the procedural texturing process is not visible yet: The generation phase needs to be activated.

- **The "generation" phase**: During this phase, the program and parameter values defined in the previous phase are interpreted and executed, in order to produce the final output(s) (in the particular case of procedural texturing: textures). The process is *realized*. Two main methods can be witnessed (see Ebert et al. 1998 for more details):
  - **Implicit generation**: In this case, the generation algorithms are analytically defined, allowing to be easily called in a random fashion. Usually, rendering engines will ask for a certain (u,v) value to be generated in the parameterization space for the given geometry upon which the procedural textures are applied. With this approach, no bitmap texture is stored in memory, usually at the cost of "expression power."
  - **Explicit generation**: Here a resolution for the final output textures is set, and the whole texture is rasterized, in one and only one step, and "baked out" as a bitmap texture, stored in central or video memory to be accessed by the rendering engine. These explicit techniques allow for a very wide range of output, referred to as "high power of expression."

In both cases, the generation phase is done by a *generation engine*.

Why Use Procedural Texturing?

The motivation for using procedural texturing can be very varied, going from speed of authoring to fast delivery of content. Here are some of the most important reasons why creators should use procedural texturing:



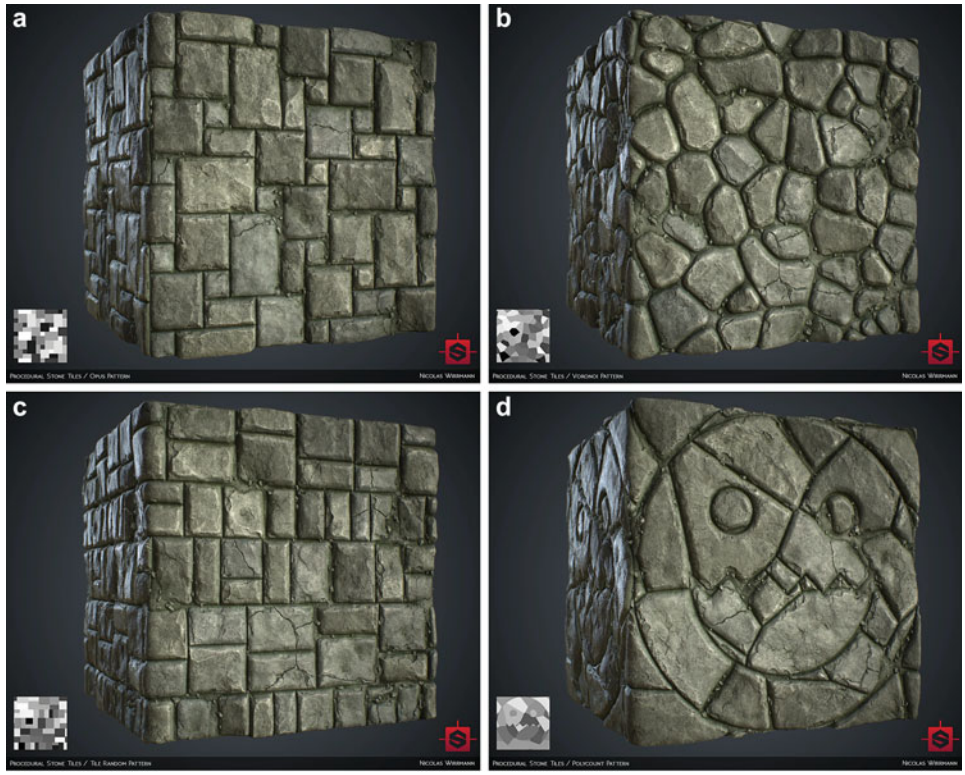
a procedural fabric material

the various texture maps necessary to the full fabric material

variations of the same fabric procedural material

The New Age of Procedural Texturing, Fig. 3 By playing on some parameter values of the procedural texturing algorithm created to generate this fabric texture, one can obtain variations in the look and feel: fabric type, level of dirt, the presence or absence of stitches, etc. (Extract from the work of Bradford Smith; see Smith n.d.)

- **Productivity**: The rise of Ultra HD and even higher resolution displays, combined with the increase in project sizes (see games such as Rockstar™'s Grand Theft Auto™ where the player can freely explore gigantic areas), again combined with the always decreasing (relative to the amount of content produced) production budgets (and margins to creators) of computer graphics and digital assets represents a significant challenge to creative teams. A large volume of assets needs to be created as quickly and cheap as possible, at the utmost levels of quality. Here procedural texturing, with its "data amplification" nature (see Ebert et al. 1998), can definitely help, as once a procedural texture definition is set and approved for one realization of the process, one can change parameters, and in particular the random seed used when generating the textures (see Ebert et al. 1998), to automatically create a theoretically infinite number of other textures. These will look like they are



The New Age of Procedural Texturing, Fig. 4 Images can be treated as input parameters of procedural texturing techniques. In these procedural materials, images at the *bottom left* are used to drive the positioning and shape of the stones in the final material (Extract from the work of Nicolas Wirrmann from Allegorithmic; see Allegorithmic et al. (2003). Logo at the *bottom left* of image **d** is the Polycount logo ("Greentooth"), the reference discussion forum when it comes to technical 3D art; see Polycount n.d.)

part of the same "family" but will be different when compared pixel by pixel (see Ebert et al. 1998). A lot of creative studios now use procedural techniques to produce very large amounts of textures, used either as is or as a building block to other more complex textures, using a combination of various creation techniques. The gains are nonlinear and higher as time passes as creators can hoard techniques and texture definitions in a library of generative, versatile content. Finally, if the art direction for the content changes at some point in the process, it is easier than ever to change one input value to all the procedural textures and then regenerate all your batch via a single command. Here again, the gains in productivity are immense.

- **Complex texture production**: Sometimes replicating an effect witnessed in nature or fantasized by an artist is not an easy task. References can be lacking, and in that case, iterations are the key to success in a trial and error process. Not having to paint a new texture for every iteration, or take a picture of an effect so it can be processed and used as a proper texture, can lead to huge time savings. Playing with parameters and simply calling again against the generation engine is a very important time saver (going back to the previous, productivity-centric point), making it a good step toward the production of the desired look. It is also worth noting that the level of complexity that noise generators especially can produce is something that is very hard to replicate by hand. Here again, procedural noise

the different textures composing the wood panel texture

The New Age of Procedural Texturing, Fig. 5 These textures (all the components of the digital materials presented here, like "albedo," "normal," "roughness," and "metallic" maps) would have been extremely complex and time-consuming to produce by hand. Procedural techniques, on the other hand, produce these textures quite easily (Extract from Joshua Lynch's online portfolio; see Lynch 2015)

generation and overall texturing techniques can prove very helpful (see, for instance, Fig. 5).

- **Look consistency**: Applying procedural generation techniques in the production of a large amount of textures can also prove very important to ensure the look consistency of the assets. Most of the time, even if not guaranteed, changing parameter values will lead to textures sharing the same visual properties. Also, by controlling the procedural techniques used by creators, one can make sure the outputs of these processes and the processes themselves respect specific properties and constraints, respectively, such as "the roughness map only contains values within a certain range," or that "the normal map is only computed after all the computation on the height maps have been done, this latter map being in grayscale 32f format instead of 24b colour for the albedo map." An automated process can definitely help ensure rules are respected and that the assets maintain a consistent look once imported in the game engine.
- **Data size optimization**: Procedural textures description files, especially when they are of the "purest" form (see "Definition" section), can be very compact. Due to the descriptive nature of procedural techniques, and the two-step process (authoring, then generation; see section "What Is a Procedural Texture?") of procedural texturing, a procedural texture description file will typically weigh a few kilobytes instead of several megabytes or

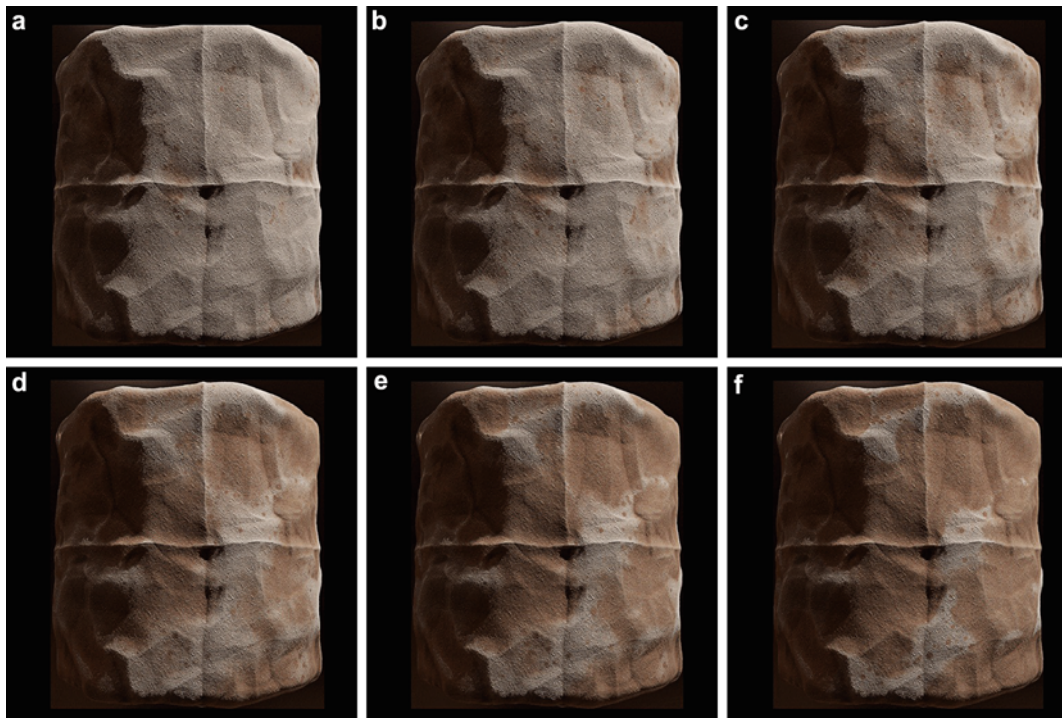
gigabytes in relation to their bitmap equivalent. This is often referred to as "data amplification" and can prove useful when the generation process can be done on the "client side": In the case of a mobile or online game, for instance, the players will only download a set of very light description files on their local device (the "client"). These files are then generated locally by the generation engine whenever they are required to display (install-, load-, or runtime). This generation process is often faster than the download time, making the benefits twofold: faster download times and lighter network consumption.

- **Animated and customized textures**: Because procedural textures are defined by parameters and generated in a two-step process through a generation engine, and in the case that generation engine is embedded in the playing application (i.e., game or virtual experience, for instance), one can modify these parameters' values at runtime and call against the engine to regenerate the output textures with a new look and feel to them. This leads to very interesting effects such as animated textures (see Fig. 6), adaptive textures (more or less dirt after an explosion occurred in the area where they are set, for instance), or simply user customization (the idea of letting the player of a game choose parameter values herself to "tweak" the look of the assets to their desire: see Fig. 7).

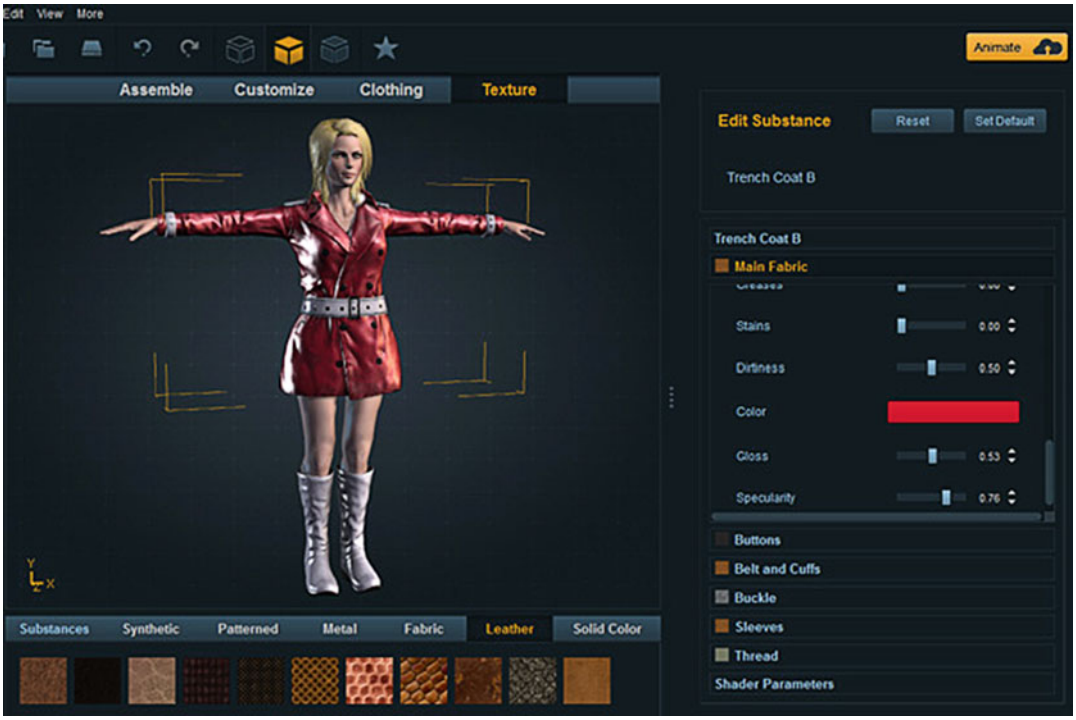
Misconceptions About Procedural Texturing

Procedural texturing has suffered in some circles from a bad reputation. Among the main misconceptions, we can cite:

- **Procedural textures look too "mathematical"**: It is true that when confined to 30+-year-old techniques, the outputs one can obtain by using "colorized" noise functions can look



The New Age of Procedural Texturing, Fig. 6 In these realizations of the same procedural texturing algorithm, defining parameters can make the fabric more wet and dirty (Extract from the work of Bradford Smith; see Smith n.d.)

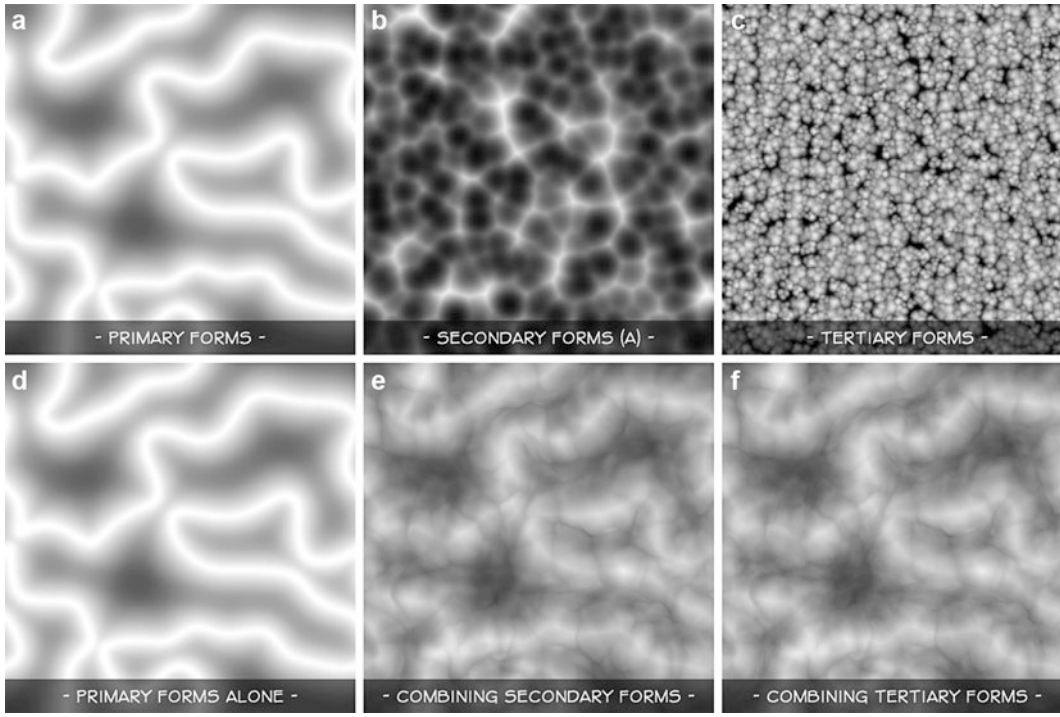


The New Age of Procedural Texturing, Fig. 7 The textures on this virtual character are fully procedural and can be controlled by the operator via the parameters on the right side of the interface (Extract from Adobe™ Fuse™; see /https://community.mixamo.com/hc/en-us/articles/203533673-Tutorial-Create-a-Character-with-Fuse)

fake or the result of a very mathematical process. Just like any other tool, procedural texturing techniques can bias outputs, so it is up to the artist to remove this by enhancing the techniques and/or use of these techniques. Combining various outputs often breaks this "mathematical look" (see Figs. 8 and 9), and today's production of procedural textures is now operating at the highest quality levels.

- **Procedural textures are only for tileable textures**: This point also inherits from 30+ years of procedural texturing techniques, the early stage of which found most techniques being used to produce square, tiling textures that would be repeated over surfaces in a way that optimized video memory usage and accesses. But there is no limitation for procedural textures to be evaluated directly onto a 3D surface and/or to take into account the geometry onto which the textures are then wrapped (see Figs. 10, 11, and 12 and tools like Substance (Allegorithmic et al. 2003)).
- **Procedural texture limits artist's creativity**: Up to now, the availability of tools and knowledge needed to advance procedural techniques were limited. This converges with an outdated view that believes procedural textures should be only evaluated at runtime, leading to techniques that produce undesired outputs, especially with regard to their artistic value. A lack of user input is indeed frustrating to artists. This aspect is now mostly outdated: See section "The New Age of Procedural Texturing" and the numerous counterexamples displayed in this article.
- **Procedural textures are "replacing" artists**: Productivity is one of the main advantages of using procedural texturing. In my observations, most studios that implement procedural texturing techniques enjoy more creation time, thanks to the practical use of these techniques. This time is then used to increase the quality of their final textures. Procedural textures are also used as a way to quickly

The New Age of Procedural Texturing, Fig. 8 This photo-realistic "Sandy Ground" procedural material is the result of the combination of several noises; see Fig. 9 (Extract from the work of Bradford Smith Adobe™ Fuse™; see Smith n.d.)



The New Age of Procedural Texturing, Fig. 9 In order to produce the procedural "Sandy Ground" material presented in Fig. 8, author Bradford Smith combined three different, procedural noise functions: (d) = (a). (e) = (a) + (b), and (f) = (a) + (b) + (c). (f) is the final result, utilized as a height (or displacement) map in Fig. 8. Although each "form" or noise function is the result of a pure mathematical process, the end result is photo-realistic (Extract from the work of Bradford Smith; see Smith n.d.)

generate a texture draft that can then be reprocessed, or sometimes completely redone, by hand. My view is that procedural texturing will only replace the mere, repetitive texturing tasks with no added value, rather than completely "replace artists": Artistic vision is still key in the texture creation process.

The New Age of Procedural Texturing, Fig. 10 This character has been textured using a procedural, nondestructive methodology offered in Allegorithmic™ Substance™ Designer™ (Extract from the work of Samuel Compain; see Compain n.d.)

- **Procedural textures are slow to compute and should only be implicitly evaluated**: A higher complexity in the procedure necessary to generate textures at the desired graphical level implies longer computation times. Combined with limited, available resources on devices, this factor can limit the spread of the techniques. Also an inherited thinking is that procedural textures are necessarily implicitly evaluated, which dramatically limits the power of expression of the techniques at hand. This point is addressed at length in section "The New Age of Procedural Texturing."
- **Procedural textures are barely used in real production**: All the limitations and misconceptions above have hindered the spread of procedural techniques in the past. That being said, and this is one of the main inspiration points behind this article, their now pragmatic use (see section "The New Age of Procedural Texturing") has helped spread usage in production. At the time this article was published, a very significant percentage (25 %+) of AAA games currently being produced make a large use of procedural techniques.

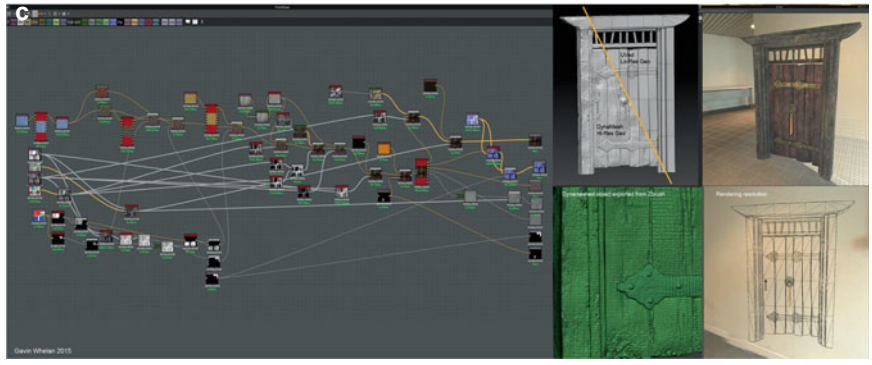
The New Age of Procedural Texturing

This new age is made possible in large part by a combination of two categories of factors: human and technical.

- **Procedural techniques at authoring time**: First, artists have realized that *procedural texturing finds maybe its best application case during the authoring phase of the content*, instead of the runtime phase. In fact,

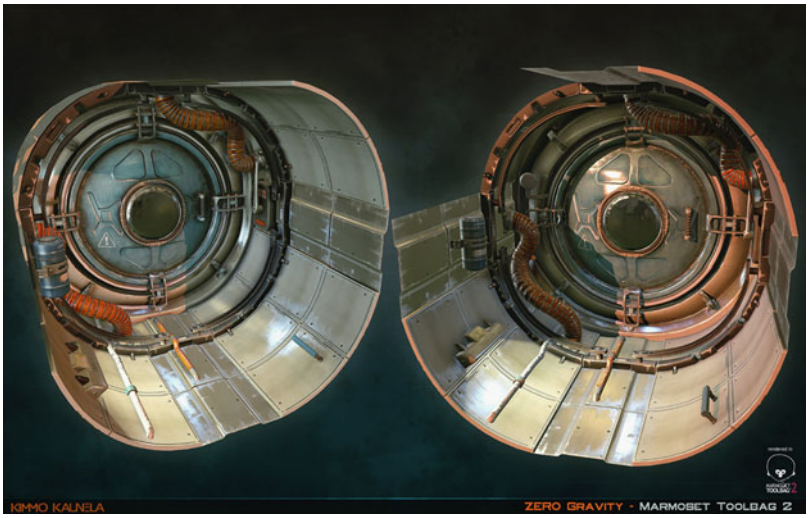
this scene has been entirely textured using a procedural approach

most of the procedural textures in this scene are not mere tiling textures, but adapted to every, specific asset



the procedural texturing process described in the graph on the left is dedicated to the door mesh on the right

The New Age of Procedural Texturing, Fig. 11 All elements composing this scene have been produced using a procedural, nondestructive methodology offered in Allegorithmic™ Substance™ Designer™ (Extract from the work of Gavin Whelan; see Whelan n.d.)



The New Age of Procedural Texturing, Fig. 12 This scene has been entirely textured using Allegorithmic™ Substance™ Designer™, a procedural texturing tool of the latest generation. Note how the mesh properties are taken into account in the process, such as on the edges of metallic parts – material is more aged in these areas (Extract from the work of Kimmo Kaunela; see Kimmo n.d.)

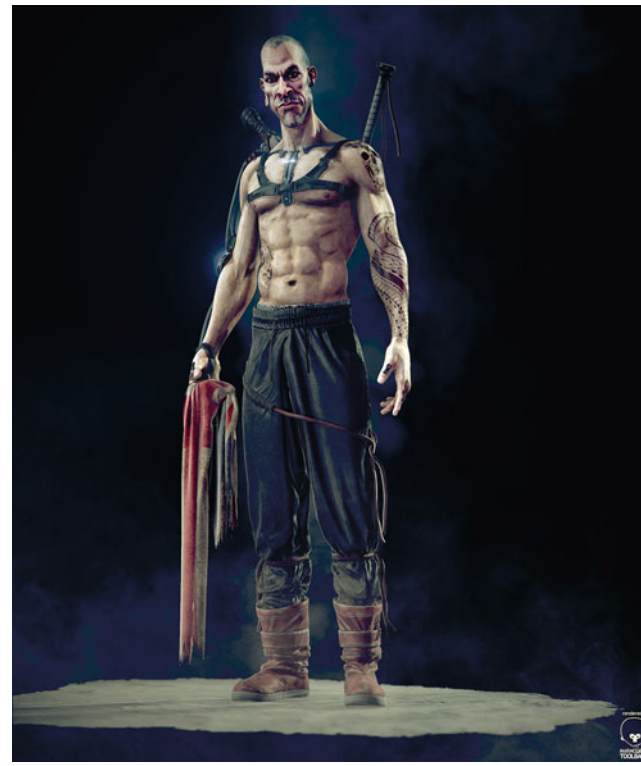
The New Age of Procedural Texturing, Fig. 13 This scene has been textured using a pragmatic approach in Allegorithmic™ Substance™ Designer™: a mix of procedural and bitmap elements (Extract from the work of Koola; see Koola n.d.)

procedural texturing in most studios today is used as a tool more than a means, and the output of this procedural texturing process is simply "baked" out as a set of bitmaps. These bitmaps can then be modified using traditional tools and techniques and consumed using traditional techniques by game and rendering engines alike. This way of using procedural techniques and tools eradicates most of the drawbacks that artists and engineers might have experienced by using procedural textures at runtime (see section "Misconceptions About Procedural Texturing").

- **A pragmatic use**: The large trend one can observe now is the *mix of techniques* used by the most advanced texture artists in the industry; using whatever tool is available and best suited for the task will be the choice of reason, and these tools and processes will be integrated in a holistic process made possible in particular by the "authoring-time" centric creation process described earlier (see, for instance, Figs. 13 and 14). This is a trend we will see getting stronger in the years to come as new artists begin to be freed from the misconceptions described in section "Misconceptions About Procedural Texturing."

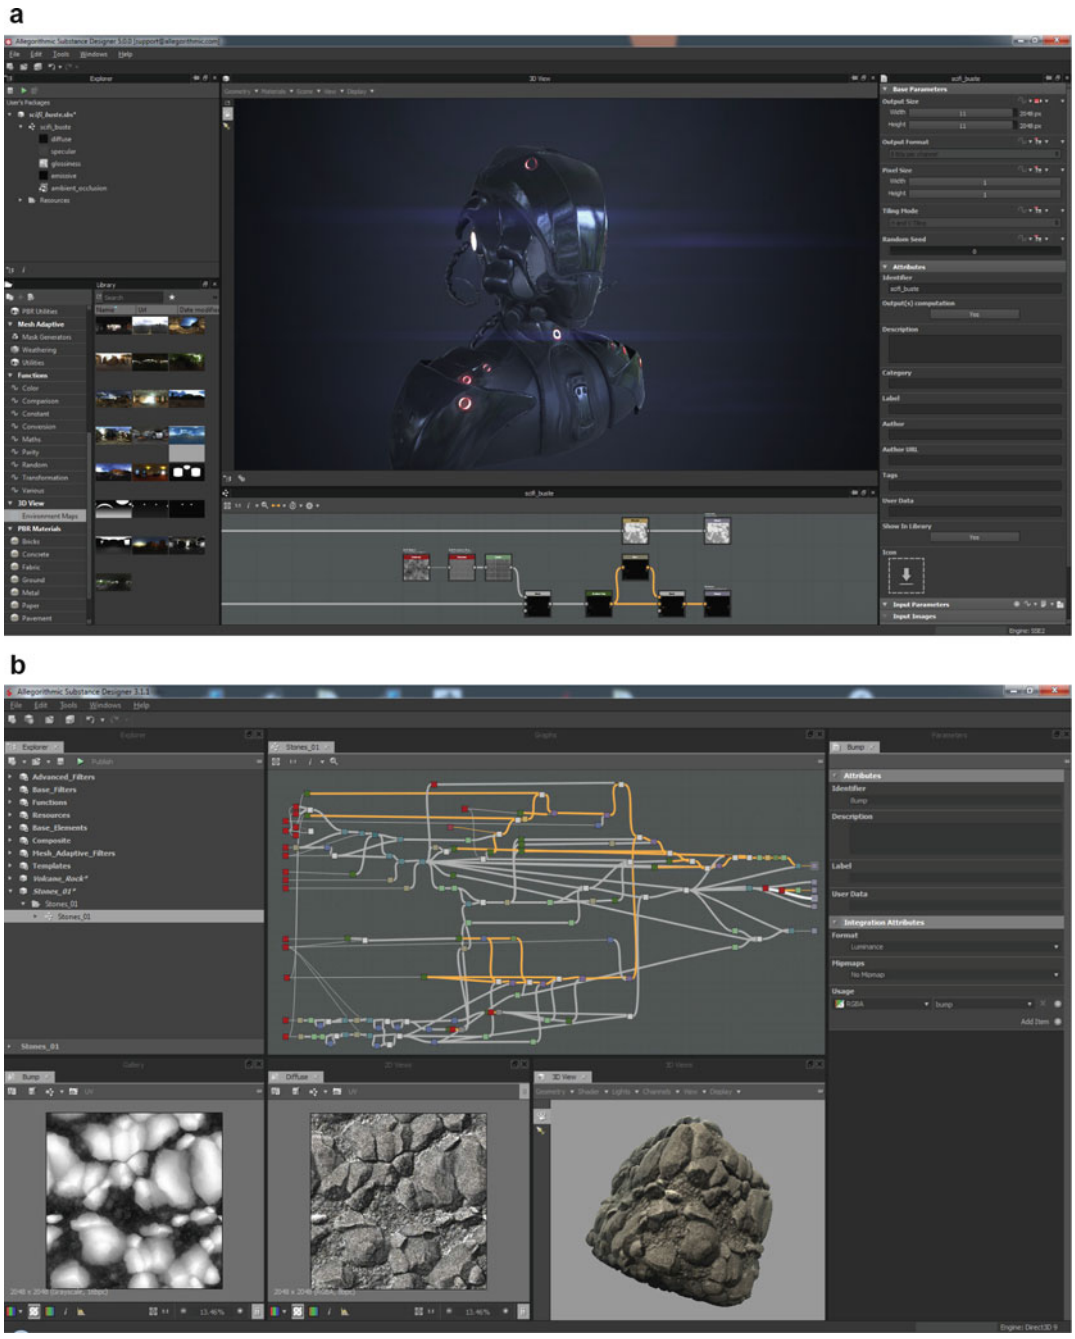
The second category of factors is technical:

- **Available computational power**: The amount of computational power available to creators, whether on desktop computers, mobile devices, or via cloud-based servers, is now higher than ever and has reached a point where generating content using procedural techniques is a viable option. Computationally expansive techniques, such as iteration-based algorithms, can now be put in practice.
- **Advances in computer science**: Techniques such as machine learning have made very important leaps in the past years, and it is to be expected that these approaches, which are based on training a set of algorithms to produce textures according to an inputted set of examples, will lead to new advances in the field.

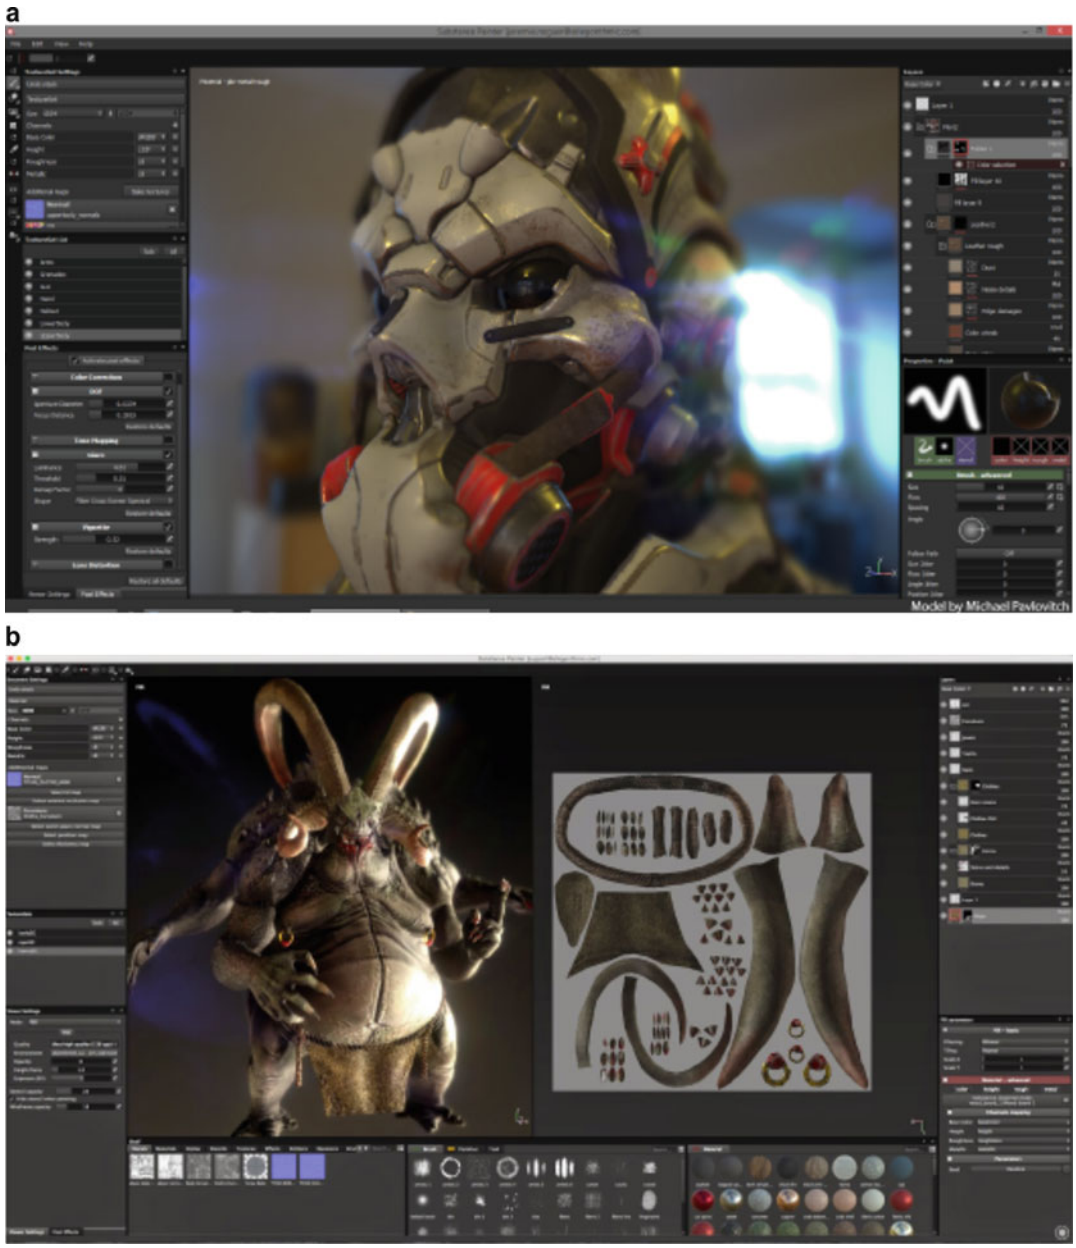


The New Age of Procedural Texturing, Fig. 14 This character has been textured using a mix of procedural techniques and handcraft. It is representative of the latest advances in texturing: a pragmatic use of all available techniques at hand, including procedural texturing (Extract from the work of Juan Puerta; see Puerta n.d.)

- **Available, more accessible tools**: Advances in UI and UX practices, combined with the rise of new tools dedicated to procedural texturing, such as the Substance™ tool suite that my company Allegorithmic™ develops of course (see Allegorithmic et al. 2003 and Figs. 15 and 16),



The New Age of Procedural Texturing, Fig. 15 Substance Designer™ by Allegorithmic™ is a tool largely (but not exclusively) dedicated to the creation of procedural textures while still being accessible to every artist, thanks to its advances in UI and UX (See Allegorithmic et al. 2003)



The New Age of Procedural Texturing, Fig. 16 Substance Painter™ by Allegorithmic™ makes a large use of procedural texturing techniques on top of more traditional hand-painting features (See Allegorithmic et al. 2003)

and others like Quixel Suite™ (see Quixel n.d.), 3DCoat™ (see 3D Coat n.d.), and the always relevant Side Effects Software™ Houdini™ (see Side Effects Software n.d.), have definitely supplanted the older generation of tools. More importantly, these tools are easy to use and do not require advanced mathematical or computer science and programming knowledge to be able to produce efficiently and professionally procedural textures. Their price points and dedicated business models make them accessible to smaller studios as well as enthusiasts, which is one more move toward the democratization of

procedural texturing. Finally, these tools are not limited or "exclusive" (in their approach) by design and embrace a novel view of procedural texturing and propose new techniques and approaches (see next section).

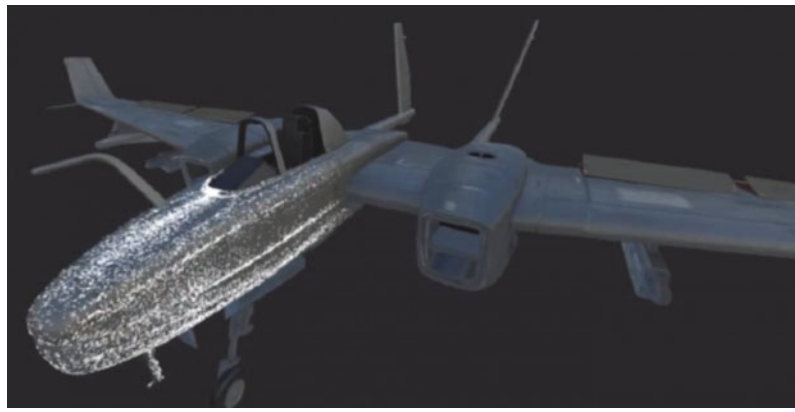
New Techniques and Tools

Maybe the most important point made in the past years by the creators of procedural texturing tools is the fact that the process has to be *hybrid*. Artists and developers alike do not want to "take on a side" anymore, whether to go full procedural or full manual. Procedural techniques, as we have seen, can now be utilized practically, and it is up to the artists to choose the technique they want to use for the particular task they have to complete. Modern tools allow for a hybrid approach, proposing procedural techniques that complement traditional hand-painting features, such as Allegorithmic™ Substance Painter™ (see Allegorithmic et al. 2003 and Fig. 16).

Other techniques have been largely improved in the recent years, adding to the arsenal of options to the artists. Techniques such as image-based texture synthesis are now widely used, and tools like Allegorithmic™ Bitmap2Material™ (see Allegorithmic et al. 2003 and Fig. 17) or more recently Artomatix™ (see Artomatix n.d.) are procedural-based tools largely used in production.

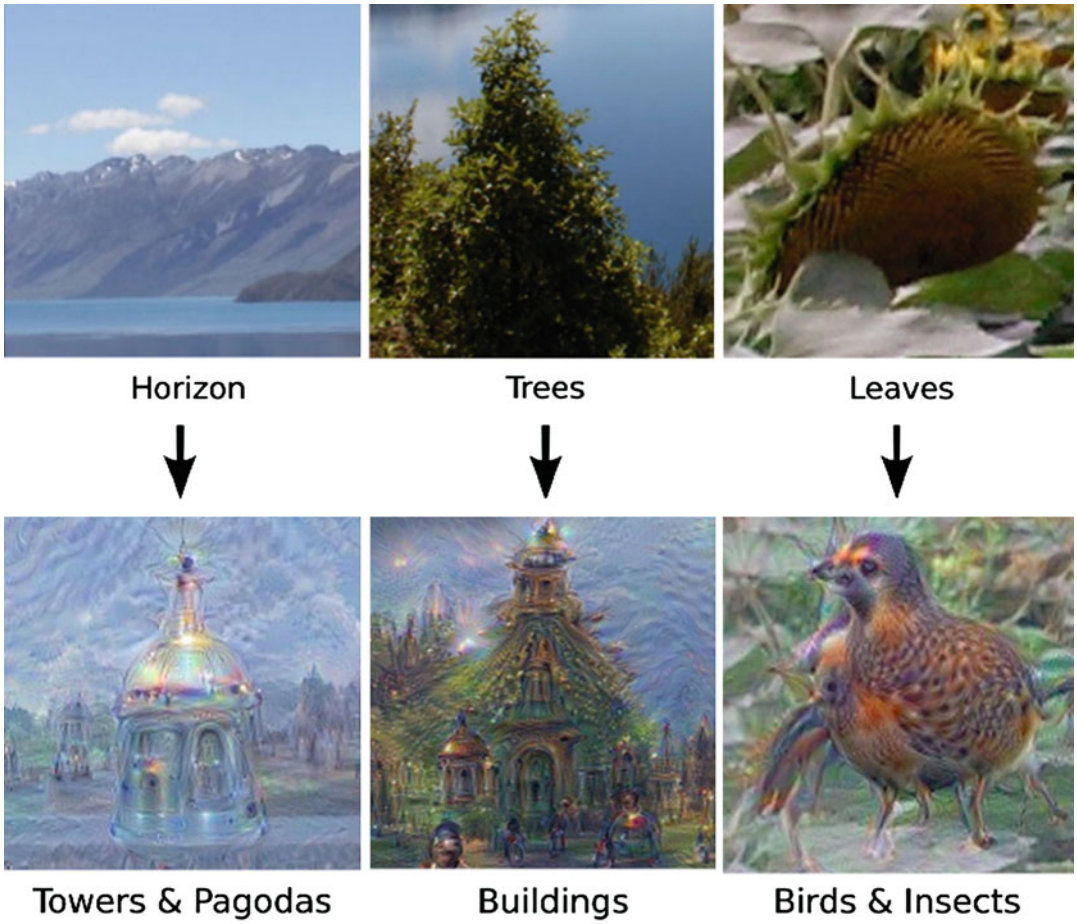
Iterative generation techniques (see, for instance, Fig. 18) have also been made practical, especially thanks to the advances in computational power. Instead of taking a long time to render (for each iteration to go through), these procedures can now be quasi real time, allowing artists to use a "trial and error" creative approach while modifying the parameters of the process in use.

Also worth noting here, and very much aligned with the idea of hybrid approaches mentioned above, Allegorithmic™ recently introduced a procedural brush system in which a particle simulation algorithm is utilized to paint over a surface, while the user controls various parameters that define the behavior of the particles, as well as the position at which the particles are spawned and directed (see Figs. 19 and 20).



The New Age of Procedural Texturing, Fig. 19 A particle simulation system is being used in Allegorithmic™ Substance Painter™ to give artists new procedural-based texture creation tools. The particles in *white* are "thrown" at the plane's nose, and, following a certain behavior, these particles will flow against the structure in a realistic way and leave dirt traces in the textures wrapped onto the plane, where they are supposed to appear (see Allegorithmic et al. 2003)

The New Age of Procedural Texturing, Fig. 20 Most of the textures on this character make use of the particle-based procedural brushes available in Allegorithmic™ Substance Painter™ (see Allegorithmic et al. 2003). Image by Christophe Desse, model by Olivier Couston. See Desse n.d.)



The New Age of Procedural Texturing, Fig. 21 The images or textures at the bottom have been "dreamt" by an algorithm developed at Google Research™. Advances in machine learning and neural networks will lead to novel procedural techniques and more effective manipulation of procedural techniques by computers and artists (See Google Research n.d.)

Finally, we can cite an area of research which will lead to more advances in procedural texturing: *machine learning* and the latest developments in recurring neural networks, as illustrated on Fig. 21 (see Google Research n.d.). These techniques will help both in producing new procedural techniques, derived from the experience and knowledge of the artists sharing their work and work process at a large scale (large enough so that algorithms can *learn* from it), as well as in the estimation of meaningful parameter spaces for a given procedural technique.

Conclusion

In this entry we have been shedding some light on what can reasonably be called a new age for procedural texturing. Procedural texturing, in itself, is a technique more than 30 years old that can have a lot of benefits but has been only very lightly used in production compared to traditional techniques. Due to major advances in computational power, to the appearance of dedicated, user-friendly tools, and to a pragmatic use of various, available techniques by

artists, today's production studios are embracing procedural texturing at a scale that has never been witnessed before. In many ways, this age is only beginning, and we predict we will see a lot more advances in this field in the years to come.

Life simulation game

Definitions

Life simulation game: Life simulation games usually have a focus on gameplay that allows players to have meaningful and complex interactions with the world around them. This interaction with the game's world usually addresses common life themes, such as farming, fishing, NPC social interaction, resource gathering, money-making, and many other themes found in day-to-day life.

History

The Sims franchise is a staple of life simulation games. Ever since the first game was released on February 4, 2000, the franchise has been extremely popular (Nutt and Railton 2003). The game started out with presets of clothing and shoes, three skin tones, five personality traits, two ages, and two genders. The first game in the series did not allow for much representation for gamers to express their individuality. As Albrechtslund (2007) puts it: "a successful life in *The Sims* [...is...] tied to a certain way of living both in gameplay and game representation."

With the popularity of the first game, Electronic Arts released *The Sims 2* on September 14, 2004. The game had changes both in design and game mechanics. The developer team, Maxis, has added new life stages to the CAS (Create-a-Sim, the interface where you design your sim), but the game still lacked considerable representation options. The second installment did add a new skin tone which brings it up to four from the previous three skin tones in the first game. The game also still only had two genders. The second installment also added a new feature to appearance which was the ability to change body mass, but there were only two options and players could not customize them. The hair given in the base game could be mixed and matched with any shirt, undergarment, and shoes. The hair additions had more diversity than the game before but became a discussion point for the future installment of the game (Griebel 2006).

The third installment in the franchise gave the game a huge facelift. *The Sims 3* was released on June 2, 2009. Like the second installment, there were changes in the game design and mechanics. The CAS options included three undertones for skin and had a slider so players could choose how dark or light the skin would be on their Sims. These new skin tone options enabled players to create sims that can be more of a faithful representation of themselves in the base game. The sliders were not just an option for the skin, but also to decide the body weight, muscle tone, and muscle definition for all genders, and breast size for females. The majority of the hair additions that came with the base game tended to be modeled from the Caucasian hair styles. This added to the discussions around the game not having more diverse options for players to represent themselves (liv3rpoolfan08 2009; siren2 2009).

The fourth installment of *The Sims 4* was released on May 6, 2013, and the game was completely different from the previous ones (McElroy 2014). This was the installment that completely changed the game design and mechanics from *The Sims 3*. There were mass improvements to the CAS features. Players could adjust the Sims bodies by dragging the features they wanted to change. There were, again, sliders for body weight and muscle mass/tone. However, there was a reversal on the skin tone options. Unlike the third installment, *The Sims 4* featured only a few numbers of skin tone swatches. The hair additions in the base game were also limited and still seem like they were modeled after the Caucasian hair styles. In the past couple of years, *The Sims 4* has had updates, added more skin tones and more hair additions to the base game. The game gave the player the ability to dress their sim, male or female, in masculine or feminine clothing. Other options were based on whether a Sim can or cannot become pregnant or whether the Sim can use the toilet standing or not. *The Sims* team has updated the game to include more items for different cultures, especially Diwali (SimGuruDrake 2017). Another big culture feature was clothing and architecture inspired by the Muslim religion (EA 2019).

The Sims franchise with the fourth installment motto was, "Unleash your imagination and create a unique world of Sims that's an expression of you! Explore and customize every detail from Sims to homes, and much more" (EA, n.d.). With this motto, players should feel like they should be represented, but many players have voiced out that they do not feel as represented. An identity they left out is that of representation of African American simmers (simmer is a self-assigned name for the members of the fanbase of the franchise).

African American simmers have voiced that the darker skin tones the game offers are ashy and there are no options for even darker tones (Jackson 2020). Although, this discrepancy was called out since the game was released, it also does not stop there. African American simmers have also dealt with the issues of poor texture quality of the afro hair. The hair represented in the game, like the ones before, still seemed like they are modeled after the European-descent-styled hairs.

A way for these types of simmers to express themselves is to use custom content (Sihvonen 2011). Custom content are objects that simmers create and post online for other simmers to

download. The addition of adding CC (custom content) to the Sims game means that those files take up space on a player's computer. Simmers are voicing their concern that players should not have to download CC just to be able to express themselves, but rather have items already in the game. These are the issues many simmers want fixed, and the team responded by saying "[...] in December, we'll be rolling out at least a hundred new skin tone swatches... with a particular emphasis on darker skin tones" (EA 2020a). Additionally, the aforementioned newsletter revealed that a slider will be featured on all swatches of skin tones which adds a further modification element.

Finally, in December 2020 holiday season, The Sims released the promised update that contains "100+ new skin tones, customization sliders for skin tones and makeup, and three improved base game hairstyles" (EA 2020b). The update came with sliders to adjust the light to dark value of each skin tone as well as a filter that categorizes the skin tones as warm, cool, or neutral.

Competition

The franchise has been ahead of the game when it comes to life simulation, but now there are indie games in production that could soon change the market of life simulation games. These games were especially highlighted in comparison due to the franchise's poor response rate to answer for the issues that the fan base voices.

One of the games that has made the Sims community excited is *Paralives*. The indie developers expanded the excitement by releasing a video of color customization which uses a color wheel on their news page and YouTube channel (Paralives, n.d.). With the color wheel, players of *Paralives* can customize their para's (A para is the *Paralives* equivalent of a sim.) hair color to whatever they want. With this feature, the game introduced the players' options to even further express themselves by recreating their own hair color which excited the Sims community due to the fact that the third Sims game introduced the color wheel which was removed in *The Sims 4*.

Another game reveal was the look of the game characters posted on their YouTube channel and *Paralives* news page. In *Paralives,* the human-like characters are called parafolks or para, like the characters in *The Sims* franchise are called sims. The equivalent of CAS in *Paralives* is *Paramaker*. Both the indie game and the fourth Sims game have similar features in their CAS. In Paramaker, players are able to change the overall shape and size of their characters' look, but the one mechanic that did not exist in *The Sims* was the option to change the height of the parafolks. This is a mechanic *The Sims* franchise never introduced to the game although simmers have the option to download a mod created by another Sims fan. Another feature that expands upon identity is the name customization that the game will have. Players have the option to give their parafolk a nickname and even a middle name. To represent those in some East Asian cultures, the team added the mechanic to have the option to flip the first and last name. The team is still thinking about more options like an artist/stage name and titles for parafolk.

As of November 2020, the indie game *Paralives* is far from being released since it is still in the early stage of development. So far, the game is attracting a wide amount of attention especially from the Sims community. This game provides game mechanics that the Sims community members have been wishing for since the third game.

Another indie game that recently drew attention is *Little Sim World*. On the game's official Twitter, an image of the character creation was shared that had a section showing the game's skin tones (@LittleSimWorld 2020). In the image, there are only ten selections. Following a review by a popular Sims YouTuber Plumbella (2020), *Little Sim World* added a slider for skin tone color. With the attention drawn to the issue, the indie team listened and added an element that would make all players able to find their own skin color in a short time. In comparison, it took years for the Sims team to address the skin tone issues. In this

light, smaller indie games seemingly have more opportunities to address these issues since they do not have to worry about longer corporate processes. The development team for Sims is under the name Maxis but is owned by Electronic Arts. This may result in the Sims development team not having as many creativity liberties as indie companies.

Little Sim World also introduced the identity of different genders. The game has the option of male and female but also includes nonbinary, transgender, intersex, and more. This option opens the doors for players to make any kind of character they want. Going along with the gender options, the game also allows romance between any characters, no matter the gender. *Paralives* also has this option but has not gone into more detail on their website or YouTube. *Paralives* introduced another parafolk named Sebastian who was openly revealed as being gay with his partner only being known by the name Lucas. *The Sims* franchise is not opposed to same-sex marriages but has not placed same-sex households in their game until more recently. *The Sims* does not give the vast amount of options to players like *Little Sim World*. Although players can create whatever gender they want in the Sims, the Sims themselves will not "identify" as that gender unless they use an outside mod.

With all of the options that indie games are providing to players in life simulation games, the market has the potential to change. When comparing *Paralives* and *Little Sim World* to *The Sims,* there are many similarities and differences. The indie games allow players to fully recreate themselves with very little limitations so far in their development process without the use of CC or mods.

With the Black Lives Matter movement and the growing acceptance of diverse identities, the staple of basic identity needs is coming to light, especially with life simulation games. *The Sims* is the most popular life simulation game from the time it was released. However, due to its slow adaptation, new indie games may have the upper hand by developing more options that offer more basic identity needs than *The Sims*. With new competition, *The Sims* franchise may need to adjust to the potentially new market to help stay in touch with players.

Introduction of Minkowski-Lorentz spaces to simplify Euclidean 2- or 3-dimensional problems.

Introduction

In this entry, the authors propose a survey on Minkowski-Lorentz spaces which are a generalization of the space-time used in Einstein's theory, equipped of the nondegenerate indefinite quadratic form

$$\mathcal{Q}_M\left(\vec{u}\right) = x^2 + y^2 + z^2 - c^2t^2$$

where (x,y,z) are the spacial components of the vector $\vec{u}$ and t is the time component of $\vec{u}$ and c is the constant of the speed of light. Computer Graphics computations involving families of circles or spheres are simplified in this space. One can note that a canal surface of the usual 3D Euclidean affine space is represented in the suitable Minkowski-Lorentz space by a curve. Moreover, in order to realize a G^1-blend between two canal surfaces, it is enough to make a G^1 join between two curves. From an affine Euclidean space $\mathscr{E}_n$ of dimension n where its usual value in Computer Graphic equals to 2 or 3, the authors define two Minkowski-Lorentz spaces of dimension $n+2$: the affine space $L_{n+1,1}$ and the vector space $\overrightarrow{L_{n+1,1}}$. The Minkowski-Lorentz space of dimension $n+2$ contains a n-dimensional paraboloid isometric to the affine Euclidean space $\mathscr{E}_n$. Moreover, an Alexandroff compactification of the affine Euclidean space $\mathscr{E}_n$ in the Minkowski-Lorentz space of dimension $n+2$ permits to develop some innovative general algorithms where the point at infinity of $\mathscr{E}_n$ is considered as a point of $\mathscr{E}_n$.

Planes, spheres, circular cylinders, and revolution cones are the basement of most computer aided software or 3D creation software. These main shapes or surfaces used in such background are easy to handle. The rapid access to their definition is due to the quadratic representation in terms of implicit equations or parametric representations. In addition the modeling geometric software need easy ways to join these elementary surfaces. One solution is the use of Minkowski-Lorentz space. The canal surfaces including Dupin cyclides, which contain tori, circular cylinders, and circular cones thanks to Alexandroff compactification, are joined by the plunge of the 3D space into a five dimensional space where the Dupin cyclides are mapped in quadratic rational Bézier curves. The G^1-join between spheres and

cylinders is completed in the new space by the G^1-join between two conics arcs. The Hugo robot (Foufou and Garnier 2004) representation can be based of all the previous elements and the join technic.

This entry presents the same formalism to manipulate families of circles or families of spheres. So a 2-sphere of $\mathscr{E}_3$ is the usual sphere, whereas a 1-sphere of $\mathscr{E}_2$ is a circle. A hyperplane is a plane in $\mathscr{E}_3$ and a line in $\mathscr{E}_2$. The $n-1$-dimensional unit sphere of the Minkowski-Lorentz space $L_{n+1,1}$ is the set representing $n-1$-spheres of the affine Euclidean space $\mathscr{E}_n$. Some uses of the Minkowski-Lorentz space $L_{4,1}$ can be found in Langevin et al. (2015) where a Dupin cyclide is built from three contact conditions or in Garnier et al. (2017) where a seahorse (Fig. 1) is built using G^1-joins between canal surfaces. These canal surfaces are computed using rational quadratic Bézier curves with mass points, the reader can refer to the articles (Garnier and Bécar 2016; Bécar 1997; Fiorot and Jeannin 1989, 1992; Goldman 2002).

Minkowski-Lorentz Spaces

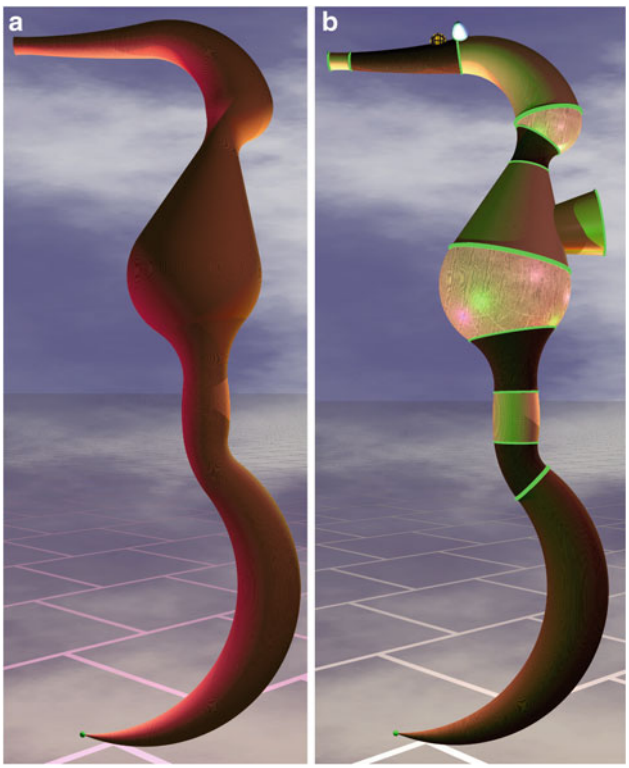
To simplify the manipulations of a family of $n-1$-spheres in $\mathscr{E}_n$, two $n+2$-dimensional spaces are introduced:

- An affine space $L_{n+1,1}$
- A vector space $\overrightarrow{L_{n+1,1}}$

Let $\left(\overrightarrow{e_i}\right)_{i\in[\![1,n]\!]}$ be an orthonormal basis for the usual Euclidean dot product of $\mathscr{E}_n$.

Definition 1 *Minkowski-Lorentz space associated to* $\mathscr{E}_n$

The Minkowski-Lorentz vector space associated to the Euclidean vector space $\overrightarrow{\mathscr{E}_n}$ *is*



Theory of Minkowski-Lorentz Spaces, Fig. 1 A seahorse modelled by G^1 blends of canal surfaces, each surface is represented by a rational quadratic Bézier curve in the Minkowski-Lorentz space. The join between two Bézier curves is G^1. (**a**) The seahorse without the dorsal fin. (**b**) The whole seahorse

$$\overrightarrow{L_{n+1,1}} = \overrightarrow{\mathbb{R}} \times \overrightarrow{\mathscr{E}_n} \times \overrightarrow{\mathbb{R}}$$

with the orthogonal basis $\left(\overrightarrow{e_-}, \overrightarrow{e_1}, \ldots, \overrightarrow{e_n}, \overrightarrow{e_+}\right)$ *equipped with the following Lorentz form, denoted* $L_{n+1,1}$ *or* $\blacksquare$, *defined as follow*

$$\begin{cases} \overrightarrow{e_-} \blacksquare \overrightarrow{e_-} = \overrightarrow{e_-}^2 = -1 \\ \forall i \in [\![1, n]\!] \cup \{+\} \overrightarrow{e_i} \blacksquare \overrightarrow{e_i} = \overrightarrow{e_i}^2 = 1 \end{cases}$$

The Minkowski-Lorentz affine space associated to the Euclidean affine space $\mathscr{E}_n$ *is defined by the point* O_{n+2} *and the Minkowski-Lorentz vector space* $\overrightarrow{\mathrm{L}_{n+1,1}}$. *All the coordinates of* O_{n+2} *are equal to zero.*

Using the point O_{n+2}, there is a one-to-one mapping between the vector space $\overrightarrow{\mathrm{L}_{n+1,1}}$ and the affine space $\mathrm{L}_{n+1,1}$

$$\forall\ \vec{u} \in \overrightarrow{\mathrm{L}_{n+1,1}}, \exists! M \in \mathrm{L}_{n+1,1} \mid \overrightarrow{O_{n+2}M} = \vec{u}$$

and

$$\forall M \in \mathrm{L}_{n+1,1}, \exists!\ \vec{u} \in \overrightarrow{\mathrm{L}_{n+1,1}} \mid \vec{u} = \overrightarrow{O_{n+2}M}$$

The point O_{n+2} is the origin of the Minkowski-Lorentz affine space $\mathrm{L}_{n+1,1}$.

The nondegenerate indefinite quadratic form associated to the Lorentz form is denoted $\mathscr{Q}_{n+1,1}$, its signature is $(n+1,1)$, and one can note that

$$\forall\ \vec{u} \in \overrightarrow{\mathrm{L}_{n+1,1}}\ \ \mathscr{Q}_{n+1,1}\left(\vec{u}\right) = \vec{u} \blacksquare \vec{u} = \vec{u}^2 \quad (1)$$

In order to simply the mathematical computations, the new basis $\left(\overrightarrow{e_o}, \overrightarrow{e_1}, \ldots, \overrightarrow{e_n}, \overrightarrow{e_\infty}\right)$ is introduced where

$$\begin{cases} \overrightarrow{e_0} = \overrightarrow{e_-} - \overrightarrow{e_+} \\ \overrightarrow{e_\infty} = \frac{1}{2}\left(\overrightarrow{e_-} + \overrightarrow{e_+}\right) \end{cases}.$$

and, in $\left(\overrightarrow{e_o}, \overrightarrow{e_1}, \ldots, \overrightarrow{e_n}, \overrightarrow{e_\infty}\right)$, the expression of the Lorentz form is obtained from

$$\begin{cases} \overrightarrow{e_o}^2 = \overrightarrow{e_\infty}^2 = 0 \\ \overrightarrow{e_i} \blacksquare \overrightarrow{e_o} = \overrightarrow{e_i} \blacksquare \overrightarrow{e_\infty} = 0 \\ \overrightarrow{e_i} \blacksquare \overrightarrow{e_j} = \delta_{ij} \\ \overrightarrow{e_o} \blacksquare \overrightarrow{e_\infty} = -1 \end{cases}. \quad (2)$$

where $(i, j) \in [\![1, n]\!]^2$ and δ_{ij} is the Kronecker Delta. The basis $\left(\overrightarrow{e_o}, \overrightarrow{e_1}, \ldots, \overrightarrow{e_n}, \overrightarrow{e_\infty}\right)$ is not an orthogonal basis given that

$$\begin{aligned} \overrightarrow{e_o} \blacksquare \overrightarrow{e_\infty} &= \frac{1}{2}\left(\overrightarrow{e_-} - \overrightarrow{e_+}\right)\left(\overrightarrow{e_-} + \overrightarrow{e_+}\right) \\ &= \frac{\overrightarrow{e_-}^2 - \overrightarrow{e_+}^2}{2} = \frac{-1-1}{2} = -1 \end{aligned}$$

The expression of the Lorentz form in this new basis follows. Let $\vec{u}(x_o, x_1, \ldots, x_n, x_\infty)$ and $\vec{v}(y_o, y_0, \ldots, y_n, x_\infty)$ be two vectors of $\overrightarrow{\mathrm{L}_{n+1,1}}$ then

$$\begin{aligned} \mathscr{L}_{n+1,1}\left(\vec{u}, \vec{v}\right) &= \vec{u} \blacksquare \vec{v} \\ &= \sum_{i=1}^{n} x_i y_i - x_o y_\infty - x_\infty y_o \quad (3) \end{aligned}$$

In the following of this section, three fundamental sets of points in the Minkowski-Lorentz affine space $\mathrm{L}_{n+1,1}$ are defined.

The Light Cone or the Null *n* + 1-Pseudosphere C_l

As the quadratic Lorentz product is a nondegenerate indefinite quadratic form, there exists some isotropic vectors. These nonnull vectors are called light-like vectors and satisfy

$$\vec{u}^2 = \vec{u} \blacksquare \vec{u} = 0$$

Thus, an isotropic vector is orthogonal to itself. Three types of vectors can be defined (Table 1).

So, a set with a particular shape is introduced: a null $n+1$-pseudo-sphere which looks like a $n+1$-dimensional cone. A position vector $\vec{m}$ defines the point m via the relation $\vec{m} = \overrightarrow{O_{n+2}m}$.

Definition 2 *The light cone C_l which is a null $n+1$-pseudo-sphere*

The light cone of the Minkowski-Lorentz affine space $L_{n+1,1}$ is the set C_l of isotropic position vectors i.e.,

$$C_l = \left\{ m \in L_{n+1,1} | = \overrightarrow{O_{n+2}m}^2 = 0 \right\} \tag{4}$$

From Formula (4), one can deduce that the distance between O_{n+2} and any point m of C_l equals zero, and the light-cone is a null-sphere of center O_{n+2} (Figs. 2 and 5). In the following of this entry, a point of $\mathscr{E}_n$ is denoted with a capital letter, its representation in the Minkowski-Lorentz is denoted with the same small letter (a vector in $\overrightarrow{L_{n+1,1}}$ or a point in $L_{n+1,1}$).

Using the reference frame $\left(O_{n+2}, \overrightarrow{e_-}, \overrightarrow{e_1}, \ldots, \overrightarrow{e_n}, \overrightarrow{e_+}\right)$, the equation of the light cone is given by

$$-x_-^2 + \sum_{i=1}^{n} x_i^2 + x_+^2 = 0 \tag{5}$$

where $(x_-, x_1, \ldots, x_n, x_+)$ are the coordinates of a point of $L_{n+1,1}$. Alternatively, using the reference frame $\left(O_{n+2}, \overrightarrow{e_o}, \overrightarrow{e_1}, \ldots, \overrightarrow{e_n}, \overrightarrow{e_\infty}\right)$, the equation of the light cone becomes

$$\sum_{i=1}^{n} x_i^2 - 2x_o x_\infty = 0 \tag{6}$$

Now, a model of $\mathscr{E}_n \cup \{\infty\}$ in the Minkowski-Lorentz affine space $L_{n+1,1}$ is presented.

The Paraboloid P Which Generates an Alexandroff Compactification of $\mathscr{E}_n$, Isometric to $\mathscr{E}_n$

Let $\mathscr{O}_n$ be the point defined by

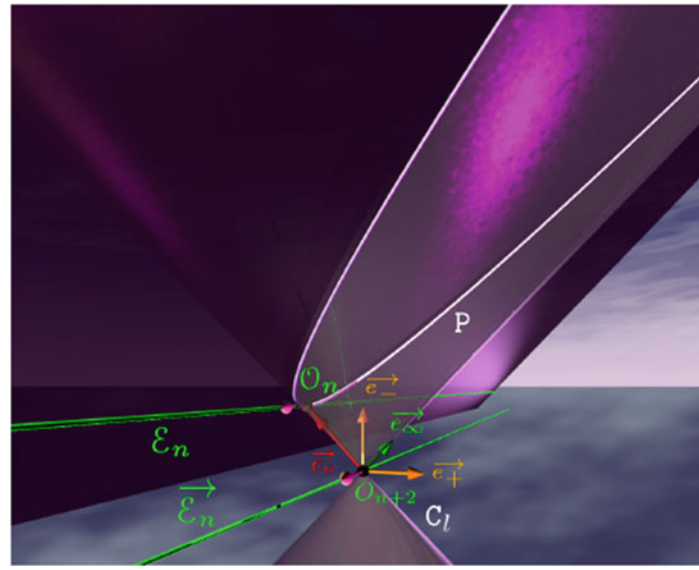
T



Theory of Minkowski-Lorentz Spaces, Fig. 3 The light cone C_l, the hyperplane $\mathscr{H}$, and the paraboloid P isometric to $\mathscr{E}_n$ and an Alexandroff compactification of $\mathscr{E}_n$ is $P \cup \{\overrightarrow{e_\infty}\}$. The green lines illustrate the Euclidean vector space $\overrightarrow{\mathscr{E}_n}$ and the Euclidean affine space $\mathscr{E}_n$

$$\overrightarrow{O_{n+2}\mathscr{O}_n} = \overrightarrow{e_o}$$

and $\mathscr{O}_n$ is the origin of the embedding $\{1\} \times \mathscr{E}_n \times \{0\}$ of the Euclidean affine space $\mathscr{E}_n$ into the Minkowski-Lorentz affine space $L_{n+1,1}$, i.e., if $(x_1,\ldots,x_n)$ are the coordinates of a point M in $\mathscr{E}_3$. The point M can be mapped to the point of coordinates $(1,x_1,\ldots,x_n,\ 0)$ in the reference frame $\left(O_{n+2}, \overrightarrow{e_o}, \overrightarrow{e_1}, \ldots, \overrightarrow{e_n}, \overrightarrow{e_\infty}\right)$. This map is one-to-one between $\mathscr{E}_3$ and $\{1\} \times \mathscr{E}_n \times \{0\}$. Now, the point $\mathscr{O}_n$ is the origin of the Euclidean affine space $\mathscr{E}_n$.

Let $\mathscr{H}$ be the affine hyperplane of $L_{n+1,1}$ defined by:

- The origin $\mathscr{O}_n$ of the Euclidean affine space $\mathscr{E}_n$
- The n space–like vectors $\overrightarrow{e_1}, \ldots, \overrightarrow{e_n}$ of the Euclidean vector space $\overrightarrow{\mathscr{E}_n}$
- The light-like vector $\overrightarrow{e_\infty}$

Let M be a point of $\mathscr{H}$, its coordinates are $(x_1,\ldots,x_n,\ x_\infty)$ in the reference frame $\left(\mathscr{O}_n, \overrightarrow{e_1}, \ldots, \overrightarrow{e_n}, \overrightarrow{e_\infty}\right)$, i.e.,

$$\overrightarrow{\mathscr{O}_n M} = \sum_{i=1}^{n} x_i \overrightarrow{e_i} + x_\infty \overrightarrow{e_\infty}$$

and then

$$\overrightarrow{\mathscr{O}_n M}^2 = \sum_{i=1}^{n} x_i \underbrace{\overrightarrow{e_i}^2}_{=1} + \sum_{i=1}^{n} (x_i \times x_\infty) \underbrace{\overrightarrow{e_i} \cdot \overrightarrow{e_\infty}}_{=0} + x_\infty^2 \underbrace{\overrightarrow{e_\infty}^2}_{=0} = \sum_{i=1}^{n} x_i^2 \tag{7}$$

the restriction to $\mathscr{H}$ of the nondegenerate indefinite quadratic form $\mathscr{Q}_{n+1,1}$ is degenerate, its signature is $(n,0)$ (the dimension of $\mathscr{H}$ is $n + 1$). Moreover, the point M is identified with $M_n\ (x_1,\ldots,x_n)$ of $\mathscr{E}_n$ and one can recognize the expression of the Euclidean scalar product of $\overrightarrow{\mathscr{E}_n}$ i.e.,

$$\overrightarrow{\mathscr{O}_n M_n}^2 = \sum_{i=1}^{n} x_i^2$$

Now, the paraboloid P can be defined.

Definition 3 *Paraboloid P*

The paraboloid P is the section of the light cone by the hyperplane $\mathscr{H}$, i.e.,

$$P = C_l \cap \mathscr{H}$$

Figure 2 shows the construction of the paraboloid P in the Minkowski-Lorentz affine space $L_{n+1,1}$.

These objects are linked thanks to the following theorem:

Theorem 1 *The equation of the paraboloid P is given by*

$$\begin{cases} x_o - 1 &= 0 \\ \sum_{i=1}^{n} x_i^2 - 2x_o x_\infty &= 0 \end{cases} \tag{8}$$

and the paraboloid P is isometric to the embedding $\{1\} \times \mathscr{E}_n \times \{0\}$ *of the Euclidean affine space* $\mathscr{E}_n$ *in the Minkowski-Lorentz affine space* $L_{n+1,1}$.

The paraboloid is a representation of the Euclidean affine space $\mathscr{E}_n$ *in the Minkowski-Lorentz affine space* $L_{n+1,1}$. *The representation of a point M* $(x_1,\ldots,x_n)$ *of* $\mathscr{E}_n$ *is the point*

$$m\left(1, x_1, \ldots, x_n, \frac{1}{2}\sum_{i=1}^{n} x_i^2\right)$$

with $\overrightarrow{O_{n+2}m}^2 = 0$.

Proof:

Formula (8) is obtained from:

- The equation of the hyperplane $\mathscr{H}$, that is, $x_0 - 1 = 0$
- The equation of the light cone C_l, that is, $\sum_{i=1}^{n} x_i^2 - 2x_o x_\infty = 0$

A one-to-one relationship between a point M $(x_1,\ldots,x_n)$ of $\mathscr{E}_n$ and the point $m(1,x_1,\ldots,x_n, x_\infty)$ is given by

$$\begin{aligned} \overrightarrow{O_{n+2}m} &= \overrightarrow{O_{n+2}\mathscr{O}_n} + \overrightarrow{\mathscr{O}_n M} + x_\infty \overrightarrow{e_\infty} \\ &= \overrightarrow{O_{n+2}\mathscr{O}_n} + \sum_{i=1}^{n} x_i \vec{e_i} + x_\infty \overrightarrow{e_\infty} \\ &= \vec{e_o} + \sum_{i=1}^{n} x_i \vec{e_i} + x_\infty \overrightarrow{e_\infty} \end{aligned}$$

The point m belongs to P if and only if m belongs to the light cone C_l. Then

$$\overrightarrow{O_{n+2}m}^2 = \sum_{i=1}^{n} x_i^2 - 2 \times 1 \times x_\infty = 0$$

leads to

$$x_\infty = \frac{1}{2}\sum_{i=1}^{n} x_i^2 = \frac{1}{2}\overrightarrow{\mathscr{O}_n M}^2$$

and the coordinates of m are

$$\left(1, x_1, \ldots, x_n, \frac{1}{2}\sum_{i=1}^{n} x_i^2\right)$$

Conversely, the projection of a point $m\left(1, x_1, \ldots, x_n, \frac{1}{2}\sum_{i=1}^{n} x_i^2\right)$ onto the embedding $\{1\} \times \mathscr{E}_n \times \{0\}$ along the direction of $\overrightarrow{e_\infty}$ is

$$m_1(1, x_1, \ldots, x_n, 0)$$

witch represents the point M $(x_1,\ldots,x_n)$ of the Euclidean affine space $\mathscr{E}_n$.

With $n = 1$, Fig. 3 shows a 3D view of the embedding $\{1\} \times \mathscr{E}_n \times \{0\}$ of the Euclidean affine space $\mathscr{E}_n$ into the Minkowski-Lorentz affine space $L_{n+1,1}$.

Note that the vector space vector $\overrightarrow{e_\infty}^{\perp}$ orthogonal to the vector space defined by the $\overrightarrow{e_\infty}$ is equal to the $n-1$-dimensional vector space

$$\overrightarrow{e_\infty}^{\perp} = \vec{\mathscr{H}}$$

T

and the authors recall that the vector $\overrightarrow{e_o}$ and $\overrightarrow{e_\infty}$ are not orthogonal. Now, the authors give the following remark:

i.e.,

$$\vec{m} = \overrightarrow{e_o} + \vec{M} + \frac{1}{2}\left\|\vec{M}\right\|^2 \overrightarrow{e_\infty} \tag{9}$$

where $\vec{M}$ *is the position vector defined by M in* $\overrightarrow{\mathscr{E}_n}$, i.e., $\vec{M} = \overrightarrow{\mathscr{O}_nM}$.

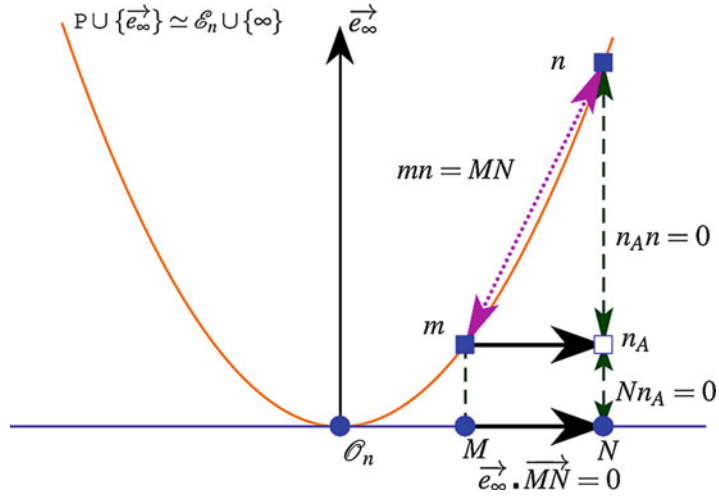
2. *The representation of the point at infinity* ∞ *of* $\mathscr{E}_n$ *is the light-like vector* $\overrightarrow{e_\infty}$.

A well-known Alexandroff compactification of the Euclidean affine space $\mathscr{E}_n$ is the hypersphere $\mathscr{S}_{n+1}$ in $\mathscr{E}_{n+1}$, and the north pole represents the point at infinity ∞ of $\mathscr{E}_n$. The following proposition offers Alexandroff compactification using the property that P is isometric to $\mathscr{E}_n$ making computations easier.

Proposition 1 *Alexandroff compactification of* $\mathscr{E}_n$

The set $P \cup \{\overrightarrow{e_\infty}\}$ *is an Alexandroff compactification of the Euclidean affine space* $\mathscr{E}_n$.

Figure 4 shows an Alexandroff compactification of the Euclidean affine space $\mathscr{E}_n$ and the isometry between $\mathscr{E}_n$ and the paraboloid P. Let M and N be two points of $\mathscr{E}_n \simeq \{1\} \times \mathscr{E}_3 \times \{0\}$. Let m and n be their representations on the paraboloid P, i.e., the point m (resp. n) is the intersection between P and the line defined



Theory of Minkowski-Lorentz Spaces, Fig. 4 Alexandroff compactification P ∪ $\{\overrightarrow{e_\infty}\}$ of the Euclidean affine $\mathscr{E}_n$ where the paraboloid P is isometric to the Euclidean affine $\mathscr{E}_n$

by the point M (resp. N) and the vector $\overrightarrow{e_\infty}$. Then

$$\overrightarrow{Mm}^2 = \overrightarrow{Nn}^2 = 0$$

The point n_A is defined as follows

$$\overrightarrow{mn_A} = \overrightarrow{MN}$$

The triangle mnn_A has two orthogonal segments ($[mn_A]$ and $[nn_A]$), using Pythagorean Theorem, it yields

$$\overrightarrow{mn}^2 = \overrightarrow{mn_A}^2 + 2\underbrace{\overrightarrow{mn_A}\cdot\overrightarrow{n_An}}_{0} + \underbrace{\overrightarrow{n_An}^2}_{0} = \overrightarrow{mn_A}^2 \quad (10)$$

which leads to

$$\begin{aligned}\overrightarrow{mn}\cdot\overrightarrow{e_\infty} &= \left(\overrightarrow{mn_A} + \overrightarrow{n_An}\right)\cdot\overrightarrow{e_\infty} \\ &= \underbrace{\overrightarrow{MN}\cdot\overrightarrow{e_\infty}}_{0} + \underbrace{\overrightarrow{n_An}\cdot\overrightarrow{e_\infty}}_{0} = 0 \end{aligned} \quad (11)$$

and any vector $\alpha\overrightarrow{AB} + \beta\overrightarrow{e_\infty}, (\alpha,\beta) \in \mathbb{R}^2$, is orthogonal to $\overrightarrow{e_\infty}$. The triangle mn_An is isosceles ($mn_A = mn$) and has two couples of orthogonal segments: the segments $[mn_A]$ and $[n_An]$ and the segments $[mn]$ and $[n_An]$.

A point of $\mathscr{E}_n$ is represented by a light-like vector in the Minkowski-Lorentz vector space $\overrightarrow{\mathrm{L}_{n+1,1}}$. Is the converse true?

The answer is given by:

Proposition 2 *Point defined by a light-like vector*

Let $\vec{m}(x_o, x_1, \ldots, x_n, x_\infty)$ be a nonnull light-like vector.

- *If $x_o = 0$, for all i in $[\![1, n]\!]$, $x_i = 0$ and the vector $\frac{1}{x_\infty}\vec{m} = \overrightarrow{e_\infty}$ represents the point at infinity of the Euclidean affine space $\mathscr{E}_n$.*
- *If $x_o \neq 0$, the vector $\frac{1}{x_o}\vec{m}$ represents the point*

$$M\left(\frac{x_1}{x_o}, \ldots, \frac{x_n}{x_o}\right)$$

of the Euclidean affine space $\mathscr{E}_n$.

The link between the Lorentz form of two light-like vectors and the distance between the corresponding points is given to end this paragraph.

Proposition 3 *Product of two light-like vectors*

Let M_0 and M_1 be two points of the Euclidean affine space $\mathscr{E}_n$.

Let $\overrightarrow{m_0}$ and $\overrightarrow{m_1}$ be two light-like vectors which represent the points M_0 and M_1.

Then

$$\overrightarrow{m_0}\cdot\overrightarrow{m_1} = -\frac{M_0M_1^2}{2} < 0$$

and

$$\overrightarrow{m_0}\cdot\overrightarrow{e_\infty} = -1$$

Proof: The system of equations

$$\begin{cases} \overrightarrow{m_0} = \vec{e_0} + \overrightarrow{M_0} + \dfrac{\overrightarrow{M_0}^2}{2}\overrightarrow{e_\infty} = \vec{e_o} + \overrightarrow{\mathscr{O}_nM_0} + \dfrac{\overrightarrow{\mathscr{O}_nM_0}^2}{2}\overrightarrow{e_\infty} \\ \overrightarrow{m_1} = \vec{e_0} + \overrightarrow{M_0} + \dfrac{\overrightarrow{M_1}^2}{2}\overrightarrow{e_\infty} = \vec{e_o} + \overrightarrow{\mathscr{O}_nM_1} + \dfrac{\overrightarrow{\mathscr{O}_nM_1}^2}{2}\overrightarrow{e_\infty} \end{cases}$$

leads to

T

$$\overrightarrow{m_0}\blacksquare\overrightarrow{m_1} = \underbrace{\overrightarrow{e_o}^2}_{=0} + \underbrace{\overrightarrow{e_o}\blacksquare\overrightarrow{\mathscr{O}_n M_1}}_{=0} + \underbrace{\overrightarrow{\mathscr{O}_n M_0}\blacksquare\overrightarrow{e_o}}_{=0} + \overrightarrow{\mathscr{O}_n M_0}\bullet\overrightarrow{\mathscr{O}_n M_1} + \frac{1}{2}\left(\overrightarrow{\mathscr{O}_n M_0}^2 + \overrightarrow{\mathscr{O}_n M_1}^2\right)\overrightarrow{e_o}\blacksquare\overrightarrow{e_\infty}$$
$$= -\frac{1}{2}\left(\overrightarrow{\mathscr{O}_n M_0}^2 + \overrightarrow{\mathscr{O}_n M_1}^2 - 2\overrightarrow{\mathscr{O}_n M_0}\bullet\overrightarrow{\mathscr{O}_n M_1}\right) = -\frac{M_0 M_1^2}{2}$$

The computation of the second case gives

$$\overrightarrow{m_0}\blacksquare\overrightarrow{e_\infty} = \left(\overrightarrow{e_0} + \overrightarrow{M_0} + \frac{\overrightarrow{M_0}^2}{2}\overrightarrow{e_\infty}\right)\blacksquare\overrightarrow{e_\infty}$$
$$= \overrightarrow{e_o}\blacksquare\overrightarrow{e_\infty} = -1$$

It is fundamental that the light-like vectors are the representations of points of $\mathscr{E}_n$ since

$$\left(-\overrightarrow{m_0}\right)\blacksquare\overrightarrow{m_1} > 0$$

Space of Oriented $n-1$-Spheres Denoted Λ^{n+1}

The representation of an oriented $n-1$-sphere in the Minkowski-Lorentz space is given in Dorst et al. (2007).

Definition 4 *Representation of an oriented Euclidean sphere of $\mathscr{E}_n$*

Let S be an oriented $n-1$-sphere of $\mathscr{E}_n$ of center Ω and of algebraic radius ρ.

The representation of S is the point σ or the position vector $\vec{\sigma}$ defined by

$$\vec{\sigma} = \overrightarrow{O_{n+2}\sigma} = \frac{1}{\rho}\left(\vec{\omega} - \frac{1}{2}\rho^2\overrightarrow{e_\infty}\right)$$
$$= \frac{1}{\rho}\left(\overrightarrow{e_o} + \vec{\Omega} + \frac{1}{2}\left(\left\|\vec{\Omega}\right\|^2 - \rho^2\right)\overrightarrow{e_\infty}\right)$$
$$= \frac{1}{\rho}\left(\vec{\omega} - \frac{\rho^2}{2}\overrightarrow{e_\infty}\right) \tag{12}$$

where $\vec{\omega}$ represents the center Ω of the sphere.

The following theorem provides an important result:

Theorem 2 *Let σ or $\vec{\sigma}$ be the representation of an Euclidean $n-1$-sphere of $\mathscr{E}_n$ in the Minkowski-Lorentz space. Then*

$$\vec{\sigma}^2 = \overrightarrow{O_{n+2}\sigma}^2 = 1$$

Proof:

$$\vec{\sigma} = \overrightarrow{O_{n+2}\sigma}^2$$
$$= \frac{1}{\rho^2}\left(\overrightarrow{e_o} + \vec{\Omega} + \frac{1}{2}\left(\left\|\vec{\Omega}\right\|^2 - \rho^2\right)\overrightarrow{e_\infty}\right)^2$$
$$= \frac{1}{\rho^2}\left(\vec{\Omega}^2 + 2\frac{1}{2}\left(\left\|\vec{\Omega}\right\|^2 - \rho^2\right)\left(\overrightarrow{e_0}\blacksquare\overrightarrow{e_\infty}\right)\right)$$
$$= \frac{1}{\rho^2}\left(\vec{\Omega}^2 + \left(\left\|\vec{\Omega}\right\|^2 - \rho^2\right)(-1)\right)$$
$$= 1$$

In the same way, the representation of an oriented hyperplane of $\mathscr{E}_n$ in the Minkowski-Lorentz space is given Dorst et al. (2007).

Definition 5 *Representation of an oriented Euclidean hyperplane of $\mathscr{E}_n$*

Let $\mathscr{P}$ be an oriented hyperplane of $\mathscr{E}_n$, this orientation is defined by the unit vector $\vec{N}$.

The representation of $\mathscr{P}$ is the point π or the position vector $\vec{\pi}$ defined by

$$\vec{\pi} = \overrightarrow{O_{n+2}\pi} = -\vec{N} - \left(\vec{N}\bullet\vec{P}\right)\overrightarrow{e_\infty} \tag{13}$$

A quick calculation gives

$$\vec{\pi}^2 = \vec{N}^2 = 1$$

and in the following of this entry, a hyperplane of $\mathscr{E}_n$ is considered as a $n-1$-sphere. The last

fundamental surface of the Minkowski-Lorentz affine space $L_{n+1,1}$ can be presented.

Definition 6 *Representation of the Euclidean $n-1$-spheres of $\mathscr{E}_n$*

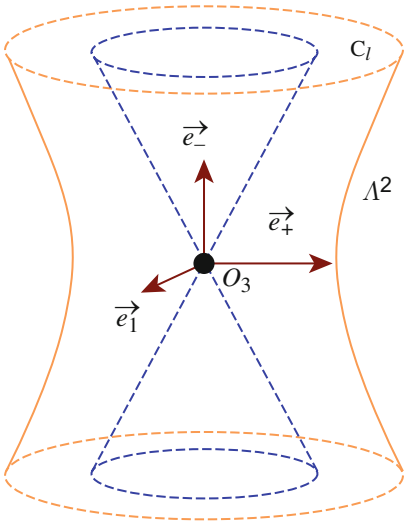
The representations of the oriented $n-1$-spheres of $\mathscr{E}_n$ belong to the unit sphere Λ^{n+1} of center O_{n+2} of the Minkowski-Lorentz affine space $L_{4,1}$ i.e.,

$$\Lambda^{n+1} = \left\{\sigma \in L_{n+1,1} | \ = \overrightarrow{O_{n+2}\sigma^2} = 1\right\} \tag{14}$$

If $n = 2$, Λ^3 is the space of circles of the Euclidean plane $\mathscr{E}_2$, whereas if $n = 3$, Λ^4 is the space of spheres of the 3D Euclidean space $\mathscr{E}_3$. Figure 5 shows Λ^2 in the 3-dimensional Minkowski-Lorentz affine space $L_{2,1}$. In the following of this entry, some constructions on Λ^n are made using Λ^2.

From Formulas (12) and (13), the representations of two oriented $n-1$-spheres (the centers are the same, the radii are opposite) S^+ and S^- of $\mathscr{E}_n$ are:

- Two unit opposite position vectors space $\vec{\sigma}^+$ and $\vec{\sigma}^-$ in the Minkowski-Lorentz vector $\overrightarrow{L_{n+1,1}}$
- Two points σ^+ and σ^- on Λ^{n+1} in the Minkowski-Lorentz affine space $Ln+1,1$, symmetric with respect to the point O_{n+2}



Theory of Minkowski-Lorentz Spaces, Fig. 5 The null sphere (i.e., the light cone) C_l of center O_3 and the unit sphere Λ^1 of center O_3

As the space of $n-1$-spheres is a surface of the Minkowski-Lorentz affine space $L_{n+1,1}$, the gradient of Λ^{n+1} at a point σ can be computed. The equation of Λ^{n+1} is given by

$$-x_-^2 + \sum_{i=1}^{n} x_i^2 + x_+^2 - 1 = 0$$

and the function f, of class $\mathscr{C}^1$, is introduced as follows.

$$\begin{array}{rccl} f: & L_{n+1,1} & \to & \mathbb{R} \\ & (x_-, x_1, \ldots, x_n, x_+) & \mapsto & -x_-^2 + \sum_{i=1}^{n} x_i^2 + x_+^2 - 1 \end{array}$$

The gradient of Λ^{n+1} at a point $\sigma(x_-, x_1, \ldots, x_n, x_+)$ is the vector

$$\overrightarrow{\nabla f}(x_-, x_1, \ldots, x_n, x_+)$$

defined by

$$d_{(x_-,x_1,\ldots,x_n,x+)} f(h_-, h_1, \ldots, h_n, h_+) = L_{n+1,1}\left(\overrightarrow{\nabla f}(x_-, x_1, \ldots, x_n, x_+), \vec{h}\right)$$

where the components of the vector $\vec{h}$ are $(h_-,h_1,\ldots,h_n,h_+)$. Note that the gradient depends on the Lorentz form

$$d_{(x_-,x_1,\ldots,x_n,x+)}f = \frac{\partial f}{\partial x_-}(x_-,x_1,\ldots,x_n,x_+)dx_- + \sum_{i=1}^{n}\frac{\partial f}{\partial x_i}(x_-,x_1,\ldots,x_n,x_+)dx_i + \frac{\partial f}{\partial x_+}(x_-,x_1,\ldots,x_n,x_+)dx_+$$

and

$$d_{(x_-,x_1,\ldots,x_n,x+)}f = -2x_-dx_- + \sum_{i=1}^{n}2x_idx_i + 2x_+dx_+$$

which leads to

$$d_{(x_-,x_1,\ldots,x_n,x+)}f(h_-,h_1,\ldots,h_n,h_+) = -2x_0h_0 + \sum_{i=1}^{n}2x_ih_i + 2x_+h_+$$

and the gradient is

$$\overrightarrow{\nabla f}(x_-,x_1,\ldots,x_n,x_+) = (2x_-,2x_1,\ldots,2x_n,2x_+) = 2\vec{\sigma} \quad (15)$$

As Λ^{n+1} is a sphere for the Lorentz product, Formula (15) is the same than the usual Euclidean formula.

The next section details that quadratic properties in $\mathscr{E}_n$ become linear in the Minkowski-Lorentz space.

Decreasing the Computation Degree

First, the conditions to determine if a point of $\mathscr{E}_n$ belongs to a given $n-1$-sphere are stated. Second, the conditions to determine the relative position of two $n-1$-spheres are given. The relation between two spheres will be used in the rest of this entry:

Definition 7 *Orthogonal spheres and relative power of two spheres*

For $i \in \{1,2\}$, let S*i be a $n-1$-sphere of center Ω_i and of radius ρ_i. The relative power $\chi_{S1,S2}$ of the two spheres S_1 and S_2 is equal to*

$$\chi_{S1,S2} = \Omega_1\Omega_2^2 - \rho_1^2 - \rho_2^2 \quad (16)$$

Moreover, the $n-1$-spheres S_1 and S_2 are orthogonal if

$$\chi_{S_1,S_2} = 0 \quad (17)$$

In fact, let A be a point of the nonempty set $S_1 \cap S_2$. The $n-1$ spheres S_1 and S_2 are orthogonal if $\Omega_1\,\Omega_2A$ is a right triangle and the segment $[\Omega_1\,\Omega_2]$ is the hypotenuse of the triangle $\Omega_1\,\Omega_2A$.

Relationship Between a Point and a $n-1$-Sphere

Four important results are given:

Theorem 3 *Relative position between a point and a sphere or a hyperplane*

Let S *be a $n-1$-sphere of $\mathscr{E}_n$, of center Ω, of radius ρ and let $\vec{\sigma}$ be its representation in the Minkowski-Lorentz vector space.*

Let $\mathscr{P}$ be a hyperplane of $\mathscr{E}_n$ passing through the point P_0, of unit normal vector $\vec{N}$ and let $\vec{\pi}$ be its representation in the Minkowski-Lorentz vector space.

Let $\vec{p}$ be the light-like vector in the Minkowski-Lorentz vector space which represents the point P of $\mathscr{E}_n$.

Then:

1. *The computation*

$$\vec{\sigma} \cdot \vec{p} = -\frac{1}{2\rho}\chi_S(P) = -\frac{1}{2\rho}\left(\Omega P^2 - \rho^2\right) \quad (18)$$

leads to

$$P \in S \Leftrightarrow \vec{\sigma} \cdot \vec{p} = 0 \quad (19)$$

2. *The computation*

$$\vec{\pi} \cdot \vec{p} = -\vec{N} \bullet \overrightarrow{P_0P}$$

leads to

$$P \in \mathscr{P} \Leftrightarrow \vec{\pi} \cdot \vec{p} = 0 \qquad (20)$$

Proof:

1. $$\vec{\sigma} \cdot \vec{p} = \left(\vec{e_o} + \vec{P} + \frac{1}{2}\left\|\vec{P}\right\|^2 \overrightarrow{e_\infty}\right) \cdot \frac{1}{\rho}\left(\vec{e_o} + \vec{\Omega} + \frac{1}{2}\left(\left\|\vec{\Omega}\right\|^2 - \rho^2\right)\overrightarrow{e_\infty}\right)$$
$$= \frac{1}{\rho}\left(\vec{P} \bullet \vec{\Omega} - \frac{1}{2}\left\|\vec{P}\right\|^2 - \frac{1}{2}\left(\left\|\vec{\Omega}\right\|^2 - \rho^2\right)\right)$$
$$= \frac{1}{2\rho}\left(-\left(\vec{P} - \vec{\Omega}\right)^2 + \rho^2\right)$$
$$= \frac{1}{2\rho}\left(-\vec{\Omega}P^2 + \rho^2\right) = -\frac{1}{2\rho}\chi_S(P)$$

Moreover,

$$P \in S \Leftrightarrow \vec{\sigma} \cdot \vec{p} = 0$$

2. $$\vec{p} \cdot \vec{\pi} = \left(\vec{e_o} + \vec{P} + \frac{1}{2}\left\|\vec{P}\right\|\overrightarrow{e_\infty}\right) \cdot \left(-\vec{N} - \left(-\vec{N} \bullet \overrightarrow{P_0}\right)\overrightarrow{e_\infty}\right) = \left(-\overrightarrow{P_0} \bullet \vec{N} + \vec{N} \bullet \overrightarrow{P_0}\right)$$
$$= -\vec{N} \bullet \overrightarrow{\mathscr{O}_nP} + \vec{N} \bullet \overrightarrow{\mathscr{O}_nP_0}$$
$$= -\vec{N} \bullet \left(\overrightarrow{\mathscr{O}_nP} + \overrightarrow{P_0\mathscr{O}_n}\right) = -\vec{N} \bullet \overrightarrow{P_0P}$$

Moreover, as $P \in \mathscr{P} \Leftrightarrow \vec{N} \perp \overrightarrow{P_0P}$, we obtain

$$P \in \mathscr{P} \Leftrightarrow \vec{\pi} \cdot \vec{p} = 0$$

The reader can note that the computation $\frac{-1}{2\rho}\left(\overrightarrow{\Omega P}^2 - \rho^2\right)$ in $\mathscr{E}_n$ is quadratic, whereas the linear computation $\vec{\sigma} \cdot \vec{p}$ in the Minkowski-Lorentz space gives the same result. The points of the paraboloid P which belong to a $n-1$-sphere are now characterized:

Corollary 1

Let S be a $n-1$-sphere of $\mathscr{E}_n$, of center Ω, of radius ρ and let $\vec{\sigma}$ be its representation in the Minkowski-Lorentz vector space.

Let $\mathscr{P}$ be a hyperplane of $\mathscr{E}_n$ passing through the point P_0, with a unit normal vector denoted by $\vec{N}$ and let $\vec{\pi}$ be its representation in the Minkowski-Lorentz vector space.

Let $\mathscr{H}_{\sigma^\perp}$ (resp. $\mathscr{H}_{\pi^\perp}$) be the hyperplane defined by O_{n+2} and its unit normal vector $\vec{\sigma}$ (resp.$\vec{\pi}$). Then

1. *The $n-1$-sphere S is the intersection between the paraboloid P and the hyperplane $\mathscr{H}_{\sigma^\perp}$.*
2. *The hyperplane $\mathscr{P}$ is the intersection between the paraboloid P and the hyperplane $\mathscr{H}_{\pi^\perp}$.*

Proof:

Let $\vec{p}$ be the light-like vector in the Minkowski-Lorentz vector space which represents the point P of $\mathscr{E}_n$.

From Formula (19), the point P belongs to the $n-1$-sphere S if and only if

$$\vec{\sigma} \cdot \vec{p} = 0$$

if and only if

$$\overrightarrow{O_{n+2}\sigma} \cdot \overrightarrow{O_{n+2}p} = 0$$

where p is the point of the paraboloid defined by

$$\overrightarrow{O_{n+2}p} = \vec{p}$$

The second property can be proved in the same way.

Relative Position of Two $n-1$-Spheres

Let i be an integer in {1,2}. Let $\overrightarrow{\sigma_i}$ be the representation on Λ^{n+1} of the $n-1$-sphere.

S_i of $\mathscr{E}_n$ of center Ω_i and of radius ρ_i. Then:

T

$$
\begin{aligned}
\overrightarrow{\sigma}\blacksquare\overrightarrow{\sigma_2} &= \frac{1}{\rho_1}\left(\overrightarrow{e_o} + \overrightarrow{\Omega_1} + \frac{1}{2}\left(\left\|\overrightarrow{\Omega}\right\|^2 - \rho_1^2\right)\overrightarrow{e_\infty}\right) \\
&\quad \times\blacksquare\frac{1}{\rho^2}\left(\overrightarrow{e_o} + \overrightarrow{\Omega_2} + \frac{1}{2}\left(\left\|\overrightarrow{\Omega_2}\right\|^2 - \rho_2^2\right)\overrightarrow{e_\infty}\right) \\
&= \frac{1}{\rho_1\rho_2}\left(\overrightarrow{\Omega_1}\bullet\overrightarrow{\Omega_2} - \frac{1}{2}\left(\left\|\overrightarrow{\Omega_1}\right\|^2 - \rho_1^2\right) - \frac{1}{2}\left(\left\|\overrightarrow{\Omega_2}\right\|^2 - \rho_2^2\right)\right) \\
&= \frac{1}{2\rho_1\rho_2}\left(-\left(\overrightarrow{\Omega_1} - \overrightarrow{\Omega_2}\right)^2 + \rho_1^2 + \rho_2^2\right) \\
&= \frac{1}{2\rho_1\rho_2}\left(-\left(\overrightarrow{\mathscr{O}_n\Omega_1} - \overrightarrow{\mathscr{O}_n\Omega_2}\right)^2 + \rho_1^2 + \rho_2^2\right) \\
&= \frac{1}{2\rho_1\rho_2}\left(-\overrightarrow{\Omega_2\Omega_1}^2 + \rho_1^2 + \rho_2^2\right) \\
&= \frac{1}{2\rho_1\rho_2}\left(-\overrightarrow{\Omega_2\Omega_1}^2 + \rho_1^2 + \rho_2^2\right)
\end{aligned}
$$

written as

$$
\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2} = -\frac{1}{2\rho_1\rho_2}\chi_{S_1,S_2} \tag{21}
$$

where $\chi_{S1,\,S2}$ is obtained from Formula (16). From Formula (21), some properties about the positions of two $n-1$-spheres can be deduced.

Proposition 4 *Relative position of two $n-1$-spheres of $\mathscr{E}_n$*

Let S_1 and S_2 be two $n-1$-spheres of $\mathscr{E}_n$ of centers Ω_1 and Ω_2, of respective radii ρ_1 and ρ_2 and let $\overrightarrow{\sigma_1}$ and $\overrightarrow{\sigma_2}$ be their representations on the space of spheres Λ^{n+1}. Then:

1. *The $n-1$-spheres S_1 and S_2 are secant if and only if $\left|\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2}\right| < 1$.*
2. *The $n-1$-spheres S_1 and S_2 are orthogonal if and only if $\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2} = 0$.*
3. *The $n-1$-spheres S_1 and S_2 are tangent if and only if $\left|\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2}\right| = 1$.*
4. *The $n-1$-spheres S_1 and S_2 are disjoint if and only if $\left|\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2}\right| > 1$.*

Proof:
Using the reals $r_1 = |\rho_1|$ and $r_2 = |\rho_2|$, Formula (21) becomes

$$
\left|\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2}\right| = \frac{1}{2r_1r_2}\left|\Omega_1\Omega_2^2 - r_1^2 - r_2^2\right| \tag{22}
$$

1. The $n-1$-spheres S_1 and S_2 are secant. Then

$$
\begin{aligned}
&|r_1 - r_2| < \Omega_1\Omega_2 < r_1 + r_2 \Leftrightarrow r_1^2 \\
&+r_2^2 - 2r_1r_2 < \Omega_1\Omega_2^2 < r_1^2 \\
&+r_2^2 + 2r_1r_2 \Leftrightarrow \left|\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2}\right| < 1
\end{aligned}
$$

2. The $n-1$-spheres S_1 and S_2 are orthogonal $\Leftrightarrow \chi_{S_1,S2} = 0 \Leftrightarrow \overrightarrow{\sigma}\blacksquare\overrightarrow{\sigma_2} = 0$.
3. The $n-1$-spheres S_1 and S_2 are external (resp. internal) tangent $\Leftrightarrow \Omega_1\Omega_2 = r_1 + r_2$ (resp. $\Omega_1\Omega_2 = |r_1 - r_2|$)$\Leftrightarrow \overrightarrow{\Omega_1\Omega_2}^2 = r_1^2 + r_2^2$

$$
\begin{aligned}
&+2r_1r_2 \quad \left(\text{resp.}\overrightarrow{\Omega_1\Omega_2}^2 = r_1^2 + r_2^2 - 2r_1r_2\right) \\
&\Leftrightarrow \left|\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2}\right| = 1
\end{aligned}
$$

.

4. The $n-1$-spheres S_1 and S_2 are disjoint, two cases are to be distinguished:

$$
\begin{aligned}
&\blacktriangleleft\Omega_1\Omega_2 > r_1 + r_2 \Leftrightarrow \Omega_1\Omega_2^2 > r_1^2 \\
&+r_2^2 + 2r_1r_2 \Leftrightarrow \left|\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2}\right| > 1
\end{aligned}
$$

$$
\begin{aligned}
&\blacktriangleleft\Omega_1\Omega_2 < |r_1 - r_2| \Leftrightarrow \Omega_1\Omega_2^2 < r_1^2 \\
&+r_2^2 - 2r_1r_2 \Leftrightarrow \left|\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\sigma_2}\right| > 1
\end{aligned}
$$

Let S_1 be a $n-1$-sphere of $\mathscr{E}_n$, of center Ω, of radius ρ and let $\overrightarrow{\sigma_1}$ be its representation on Λ^{n+1} in the Minkowski-Lorentz vector space. and then

$$\overrightarrow{\sigma_1}\blacksquare\overrightarrow{\pi_1}=\frac{1}{\rho_1}\overrightarrow{\Omega_1P_1}\bullet\overrightarrow{N_1} \tag{23}$$

and an important result can be given:

Proposition 5 *Relative positions of a $n-1$-sphere and a hyperplane of $\mathscr{E}_n$.*

As a point is a degenerate sphere, i.e., the radius is 0, one can remark:

Remark 2

Let Ω *a point of* $\mathscr{E}_3$ *and* $S(\rho)$ *a family of* $n-1$*-spheres of centers* Ω *and of radii* ρ.

The representations of $S(\rho)$ *on* Λ^{n+1} *are* $\vec{\sigma}(\rho)$. *Formulas* (9) *and* (12) *lead to*

and then, the limit of the vectors $\vec{\sigma}(\rho)$ *is the vector* $\vec{\omega}$ *which represents the center of the* $n-1$*-spheres.*

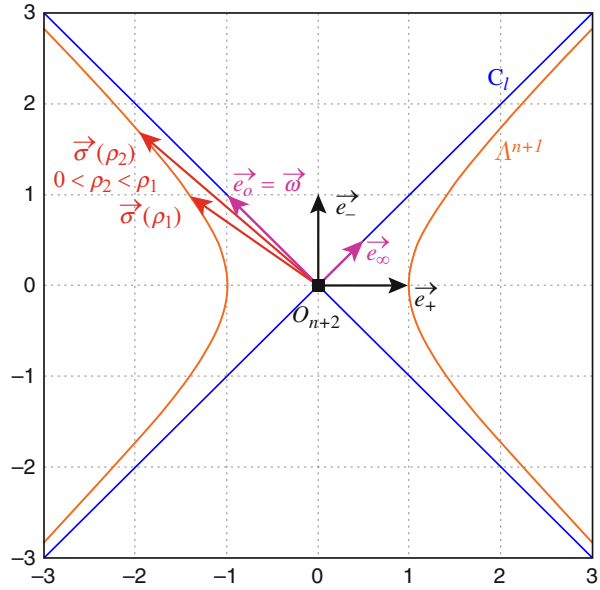
$$\Omega = \mathscr{O}_n$$

and

$$\vec{\sigma}(\rho) = \frac{1}{\rho}\overrightarrow{e_o} - \frac{\rho}{2}\overrightarrow{e_\infty}$$

and in the 2-plane defined by O_{n+2} and the light-like vectors $\overrightarrow{e_o}$ and $\overrightarrow{e_\infty}$, the representations of the $n-1$-spheres belong to a unit circle of center O_{n+2}. The equation of this circle in the reference frame $\left(O_{n+2}, \overrightarrow{e_o}, \overrightarrow{e_\infty}\right)$ is $x_o\, x_\infty = 1$,



Theory of Minkowski-Lorentz Spaces, Fig. 6 When the radii ρ of the $n-1$-spheres $S(\rho)$ of center Ω tend to 0, the representations $\vec{\sigma}(\rho)$ of $S(\rho)$ belong to an unit circle and tend to the light-like vector $\vec{\omega}$ representing the point Ω. The two lines which define the light-cone C_l are the asymptotes of the unit circle which looks like a rectangular hyperbola

whereas its equation in $(O_{n+2}, \overrightarrow{e_+}, \overrightarrow{e_-})$ is $x_+^2 - x_-^2 = 1$.

Envelope of $n-1$-Spheres

In this section, a one-parameter family $\mathscr{F}$ of oriented $n-1$-spheres S(t) of $\mathscr{E}_2$ or $\mathscr{E}_3$ is considered. If the envelope exists, each sphere of this family is tangent to the envelope S along a characteristic $n-2$-sphere. If $n=3$, a canal surface is obtained among others like quadrics of revolution or Dupin cyclides. Some conditions to obtain a canal surface are given in Langevin and Solanes (2011).

Naturally, the representation of $\mathscr{F}$ in the Minkowski-Lorentz space is a curve $t \mapsto \sigma(t)$ on $\Lambda^{n+1} \cup \mathscr{I}$ where $\mathscr{F}$ is $\varnothing$ or a set of light-like vectors which represents the degenerate $n-1$-spheres of the family or the point at the infinity of $\mathscr{E}_n$. A characteristic $n-2$-sphere is the intersection between two $n-1$-spheres: one is belonging to $\mathscr{F}$ and the other must be computed. To do that, the notion of derivative sphere is introduced.

Definition 8 *Derivative sphere*

Let $t \mapsto \sigma(t)$ be a curve, defined on the interval I, on Λ^{n+1} in the Minkowski-Lorentz space representing a one-parameter family $\mathscr{F}$ of oriented $n-1$-spheres $S(t)$ of $\mathscr{E}_n$ such that

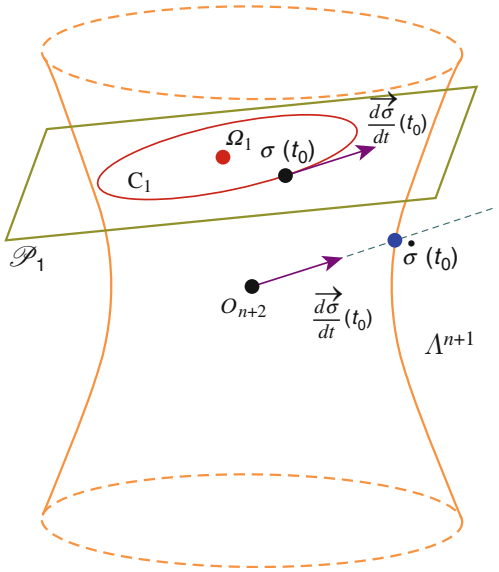
$$\forall t \in I, \quad \left(\overrightarrow{\frac{d\sigma}{dt}}(t)\right)^2 > 0$$

The derivative sphere of the sphere $\sigma(t_0)$ is the sphere $\dot{\sigma}(t_0)$ defined by

$$\left\{\dot{\sigma}(t_0)\right\} = \left[O_{n+2}, \overrightarrow{\frac{d\sigma}{dt}}(t_0)\right) \cap \Lambda^{n+1} \qquad (26)$$

The derivative sphere of the sphere $S(t_0)$ is the sphere $\dot{S}(t_0)$ defined by $\dot{\sigma}(t_0)$ (Fig. 7).

The characteristic $n-2$-sphere is the intersection between the $n-1$-sphere S (t_0) and the $n-1$-sphere $\dot{S}(t_0)$. Moreover, these two spheres S(t_0) and $\dot{S}(t_0)$ are orthogonal: from the relation



Theory of Minkowski-Lorentz Spaces, Fig. 7 On Λ^{n+1}, construction of a characteristic $n-2$-sphere when the curve C_1 defined by the one-parameter family F is a circle

$$\forall t_0 \in I, \quad \overrightarrow{O_{n+2}\sigma(t_0)}^2 = 1$$

and after derivation, the following formula is obtained

$$\overrightarrow{O_{n+2}\sigma(t_0)} \cdot \overrightarrow{O_{n+2}\dot{\sigma}(t_0)} = 0.$$

Moreover, if the spheres $\sigma(t)$ define a circle C_1 on Λ^{n+1}, the center Ω_1 of C_1 is the orthogonal projection of the center O_{n+2} of the unit sphere Λ^{n+1} onto the 2-plane $\mathscr{P}_1$ defined by C_1 (Fig. 7).

A Dupin cyclide is a canal surface in $\mathscr{E}_3$ in two equivalent ways. Figure 8 shows a characteristic circle on a horned Dupin cyclide obtained as intersection of two perpendicular 2-spheres $S(t_0)$ and $\dot{S}(t_0)$. The centers of the 2-spheres belong to an ellipse or to a hyperbola.

Figure 9 shows an other canal surface. The center of the spheres belong to the curve

$$\gamma_0(u_0) = (8\cos((u_0)); 8\sin(u_0), u_0)$$

with $u_0 \in \left[-7\frac{\pi}{2}; 9\frac{\pi}{2}\right]$ and the radii of these spheres are $R(u_0) = \cos^2(u_0) + \frac{1}{4}$.

Conclusion

This entry presents a survey on the Minkowski-Lorentz space and its interest for Computer Graphics. In a future entry, the representation of spheres in the Minkowski-Lorentz space is applied to solve classical geometric problems like Apollonius problems or some Dupin problems and the determination of an envelope of a family of oriented circles or spheres.

Definition

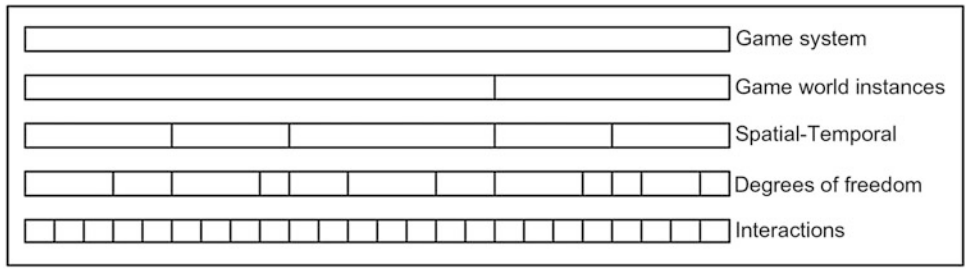
Timed Automata is a formalism for modelling and verification of time-critical systems. It has been proven to be a formalism that is well adapted to the expression of the timing constraints appearing in interactive scores and video games, because it is a powerful model for describing both the logical ordering of the events in such scenario and also the duration of events and the timing between them.

Introduction

As coined by Espen Aarseth in his very first editorial launching the "game studies" journal (considered as one of the core events establishing "game studies" as an academic field), games are "*both object and process [which] must be played. Playing is integral, not coincidental [. . .]. The complex nature of simulations is such that a result cannot be predicted beforehand; it can vary greatly depending on the players luck, skill and creativity.*" (Aarseth 2001). Activating a video game requires a processing of player(s) inputs, directly impacting the game system evolution, both **temporally** (unfolding the game narrative and ludic progression) and **conditionally** (tailoring the game accordingly to the player behavior and the gameplay elements reactions).

Segmenting play Since early ("*vintage*") arcade games, temporal and conditional (i.e., challenge) segmentation of gameplay have been considered as core perspectives to simultaneously design and analyze video games (Zagal et al. 2008). In games, time is employed as a resource (divisions, temporal limit, etc.) and/or a coordination mechanism (rounds, turn-taking, narrative key moments, etc.) (Zagal et al. 2008, p. 180). Challenges, on their sides, condition the way player(s) can interact with a game system (a change in challenge is, in general, accompanied by a change of allowed activations). Another segmentation identified by Zagal et al. is the *spatial* one, which is the "*division of the gameworld into different spaces that also partition the gameplay*" (Zagal et al. 2008, p. 182). The spatial segmentation is tied to the creative process of level designing, itself tied to the notion of **hierarchy**. Indeed, a *level* can be seen as a spatial segment containing specific *gameplay elements*, themselves interactable regarding the current *degree of freedom* enabled to the player. It is noteworthy that other game studies research, such as the six dimensions of implication identified by Gordon Calleja (2011), also regularly encompass time (narration, emotion), condition (ludic, kinesthesic, social), and space/hierarchy (strategy).

Hierarchy in games Segmenting a video game hierarchically has also been suggested by Raphaël Marczak as part of the *Gameplay Performance Segmentation model* (Marczak 2014, chapter 4), which defines five hierarchical layers of



Timed Automata for Video Games and Interaction, Fig. 1 The five hierarchical layers of the Gameplay Performance Segmentation model. (Marczak 2014, chapter 4)

analysis, toward the understanding of how a specific player actually engaged with a specific game system, contextualizing each interaction from within the whole game system: the game system layer represents to top level, then including different game instances, themselves separated in different time and space segments, containing different phases conditioning the level of freedom offered to a player at a given time, to the bottom level being the actual interaction performed by the player (see Fig. 1).

Gameplay elements themselves are hierarchically related, as emphasized by the *Game Ontology Project* (Zagal et al. 2005), classifying gameplay concepts by affiliations and groups of dependencies. For example, a *head up display* in a first person shooter game is part of *visual output*, itself part of *sensory output*, part of *presentation*, and finally part of the top theme *interface*.

Example An example illustrating the three segmentation axis emphasized above (time, condition, and hierarchy) can be seen on Fig. 2, displaying a boss fight in the game *The Legend of Zelda: The Windwaker HD* (Nintendo 2013). In terms of *hierarchy*, this boss fight happens in an enclosed arena, in which the player's avatar (Link) can find specific items in relation with the fight (mostly life-regenerating items), and the actual boss (itself subdivided into three main components: two hands and a head). *Time-wise*, the boss behavior follows a pattern during which it opens and closes its hands, mouth, and eyes, and moves within the arena. This pattern has to be learned by the player in order to correctly defeat the boss (shooting its eyes and mouth). In terms of *conditions*, the player must switch between weapons (arrow, bomb, etc.) in order to react accordingly to the boss current pattern. Each weapon has its own control and impacts the game space differently. This simple example illustrates how these three axis work concurrently.

Another example of time, condition, and hierarchy segmentation can be read in Marlène Dulaurans and Raphaël Marczak paper about the game *Clash Royal* (Dulaurans and Marczak 2018).

Game engines, such as *Unreal Engine*, *Unity3D*, *Godot*, *Game Make Studio* (to name a few), are now widely available to game designers, developers, and the general public, for supporting game making whether in companies or for independent creatives. Time, condition, and hierarchy are all encompassed in these engines, but as separated elements, and rarely displayed all-together in the same interface and representation. In *Unity3D,* for example, hierarchy is linked with graphical entities (a gameobject can be a child of another gameobject); condition is part of the C#/javascript scripting feature, or for animators; and time is managed by the game engine scheduler (calling update functions each frame) or by the scripting ability to change level/scene. Other engines, like *Unreal Engine*, *Godot* or *Game Make Studio* also have a blue-print feature, making visual the conditional possibilities.

These three main features constituting a gameplay are included in all game engines software, **but they are not part of a general scenario/representation structure, able to, at the same time, model time, condition, and**

Timed Automata for Video Games and Interaction, Fig. 2 A boss in Zelda The Windwaker HD (Nintendo 2013), illustrating the three main segmentation axis: time, condition, and hierarchy

hierarchy. For that reason, during the last few years, a promising interactive score system called *i-score* (https://ossia.io/) has been emerging with the main objective of blending together the above three features for performing art and video games. This software can be seen as a (1) *conductor* (in the musical sense), scheduling media with the flexible time concept, and as a (2) *Master Hand* (in the role playing sense), structuring a game design both temporally, conditionally, and hierarchically.

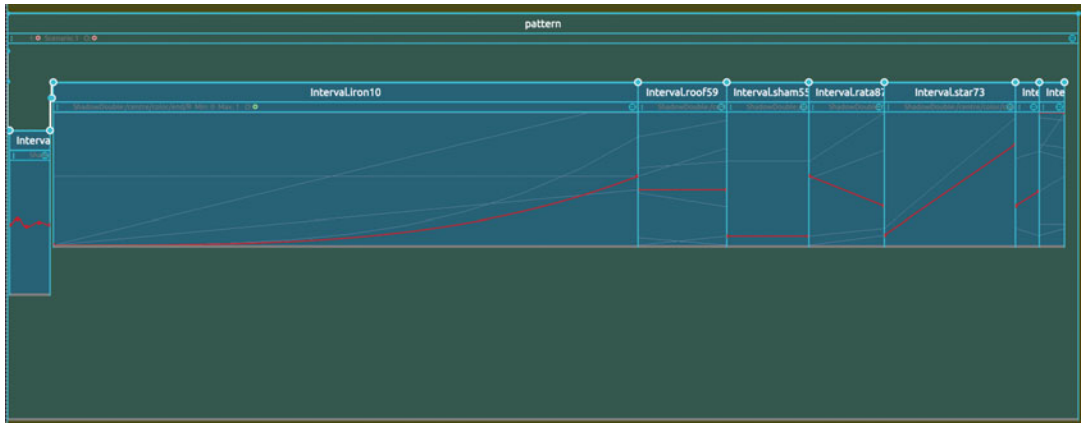
Interactive Scores with i-score

i-score provides a theoretical framework and a graphical application for the authoring and execution of interactive scores. Interactive scores consist of a temporal and hierarchical organization of events that allow users to describe interactions of the performer during the performance of the score. These interactions allow the possibility for a score to have more than one different possible performances.

The graphical model for i-score was introduced by Celerier et al. 2015. This model is based on hierarchy of graphical elements whose semantics allows to describe the flow of time. Moreover, it is adapted for the authoring of automation and processes which are happening over a duration of time, either fixed or dependent on interactive events (see Fig. 3). i-score is closer in mind to sequencers like Reaper®, Ableton Live®, or Avid Pro Tools®, than music notation software such as Finale®, Sibelius® or Bach®. For instance, Fig. 3 shows an i-score score controlling over time the brightness, the intensity, and the colors of a light projected on a surface in order to play with the spectators' perception of time and lead them to a more thoughtful mental state.

In general, interactive scores are described by powerful expressive models similar to full-fledged programming languages, e.g., the programming language for real-time and interactive computer music *Chuck* (Wang et al. 2015). The above has the main consequence of putting the users in front of the common problems that occur during the activity of programming, leading to undesired behaviors during the performance: bugs, data races, and specification problems. Hence, the need for advance verification techniques for interactive score software becomes necessary.

Multiple families of formal methods, such as Petri nets (Desainte-Catherine et al. 2013; Arias et al. 2014), process calculi (Toro et al. 2014; Olarte and Rueda 2009), and linear logic (Arias et al. 2015a), have been proposed to give formal semantics to i-score, with the goal of performing static verification on the score in order to prevent unwanted situations during the performance. However, the proposed models do not support (1) flexible control structures such as *conditionals* and (2) practical mechanisms for the *automatic verification* of scores.



Timed Automata for Video Games and Interaction, Fig. 3 Interactive score controlling over time a light projected on a surface in order to play with the spectators' perception of time and lead them to a more thoughtful mental state. Score created by The Baltazars (http://www.baltazars.org/)

In 2015, a novel model of i-score using Timed Automata was defined (Arias et al. 2015b). This model expresses, in the same framework, the main features of interactive scores (i.e., time, conditions and hierarchy). Moreover, it allows to verify the written scores automatically. Timed Automata has been proven to be a formalism that is well adapted to the expression of the timing constraints appearing in an interactive score following system (Sanchez and Jacquemard 2016; Echeveste et al. 2013; Jacquemard and Poncelet 2016), because it is a powerful model for describing both the logical ordering of the events in such scenario and also the duration of events and the timing between them.

In the next, a formal definition of Timed Automata model is presented and also some important properties of interactive scores that can now be proven.

Formal Verification of Interactive Scores in i-score

Timed Automata (Alur and Dill 1994) is a formalism for modelling and verification of time-critical systems. A timed automaton (see Fig. 4) is a finite-state machine with a finite set of real-valued variables modelling logical *clocks*. A *transition* in a timed automaton (represented by an edge) is labelled with a *guard* (i.e., when is it allowed to take an edge?), an *action* (i.e., what is performed when taking the edge), and a set of clocks (i.e., which clocks must be reset). A *location* (represented by a node) is equipped with an *invariant* that constrains the amount of time that may be spent in that location. In that sense, invariants ensure the progress of the model while guards restrict the behavior of the timed automaton. Both invariants and guards are *clock constraints* that are formally defined in Definition 1.

Definition 1 A *clock constraint* δ over a set C of clocks is defined inductively by

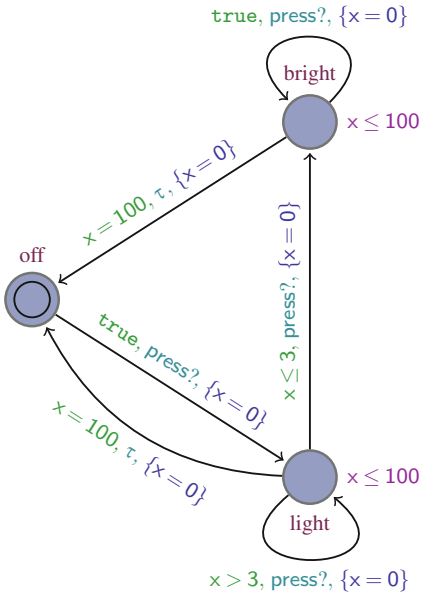
$$\delta ::= x \sim n \mid \delta_1 \wedge \delta_2 \mid \text{true}$$

where $n \in \mathbb{N}_0, \sim \in \{=, <, >, \leq, \geq\}$, and $x \in C$. Let $\Phi(C)$ denote the set of clock constraints over C, and $\Phi_<(C)$ the set of *downward closed* clock constraints of the form $x \leq n$ and $x < n$.

The formal definition of a timed automaton is as follows.

Definition 2 A *timed automaton* is a tuple $\langle L, l_0, \Sigma, C, E, I \rangle$, where

- L is a finite set of *locations*.
- $l_0 \in L$ is the *initial* location.



Timed Automata for Video Games and Interaction, Fig. 4 A light switch modelled as a timed automaton. (Fahrenberg et al. 2010)

- Σ is a finite alphabet denoting *actions*.
- C is a finite set of *clocks*.
- $E \subseteq L \times \Phi(C) \times \Sigma \times 2^C \times L$ is the set of transitions between locations.
- $I: L \to \Phi < (C)$ assigns invariants to locations.

Figure 4 shows the timed automaton model of the intelligent light switch defined in (Fahrenberg et al. 2010). The initial state of the model is off that listens for the pressing of the button in order to turn the light on (i.e., state light). Once the light is on, it waits for 100 time units (i.e., until clock $x = 100$). If an additional press is done during this time, the clock x is reset and prolongs the time in the state by 100 time units, otherwise the light turns off again. Pressing the button twice, with at most three time units between the presses, triggers a special bright light.

The Timed Automata model for i-score scores was formalized in (Arias et al. 2017, 2015b). Currently, i-score is equipped with an automatic tool for translating scores into their equivalent Timed Automata model. It covers a strict subset of i-score because the latter is based on a plug-in architecture which is easily extensible. For instance, a plug-in allowing to run arbitrary Javascript code.

The verification of scores is carried out using the UPPAAL (David et al. 2015) model-checker, which allows for the verification of networks of Timed Automata using the method of model-checking (Clarke et al. 2018). Roughly speaking, model-checking is a computer-assisted method for the analysis of systems that explores exhaustively all possible system states in a systematic manner in order to check whether a model of the system satisfies a given property.

Once the Timed Automata model of the score is generated by i-score, it is possible to check the following useful properties with UPPAAL:

- The temporal exclusivity of two multimedia processes P_1 and P_2. That means that in all possible executions of a score, always both P_1 and P_2 are not executed at the same time. This is important, for instance, if a multimedia device can only handle one automation at the same time.
- The unreachability of an *error* state. That is, in all possible executions of the score, all the multimedia processes never reach an error state (i.e., all the temporal constraints of the system are always satisfied).
- It is possible to assert that given an annotation of the multimedia processes relative to the part they pertain to (e.g., Intro, Chorus, Verse), the score's structure satisfies a specific order. For instance, the Intro is always followed by a Chorus.

Applications to Games and Interaction

In the following, two special applications of i-score in the domain of games and interaction are presented.

SEGMent

SEGMent (*Study and Education Game Maker and entertainment*) is a diagram-based game making language allowing anyone willing to create (digital) escape games to compose multimedia scenarios without any programming skill

pre-required. From the three main phases of game-making process, being conception (brainstorming, story-boarding, proof of concept, etc.), implementation (technical programming of the game) and experience (gameplay metrics gathering (Drachen and Canossa 2009; Marczak et al. 2015) for analysis and understanding); SEGMent is handling the two intimidating ones from non-computer scientist perspective (implementation and experience), so that anyone, from professors, students to game designer, can fully focus on the conception phase. The main objective of SEGMent is to help teachers create ludo-pedagogical experiences in relation to their discipline, in the form of an escape game (including still images, sounds, animations, videos, digicode/keypad behavior for user input, object states, etc.), by the simple drawing of a diagram. The main features of SEGMent are:

- Scenes background creation.
- Objects addition in scenes (hierarchically).
- Click areas to go from one scene to another (hierarchically).
- Background atmospheric sound for scenes.
- Possibility to interact with objects and change their states (condition).
- Object animation when changing state (time).
- Self-reflexive dialog the first time a user enters a scene (time).
- Possibility to interact with areas on screen to generate input (like digicode or keyboard) (condition).
- Possibility to move elements as puzzle pieces (condition).
- Possibility to go from one scene to another by entering an answer (manually or with generated input) or by having several objects in specific states (condition).
- Possibility to go directly to another scene after a specified amount of time (time).
- Possibility to go back to the previous scene (time), etc.

From SEGMent to SEGMent^2

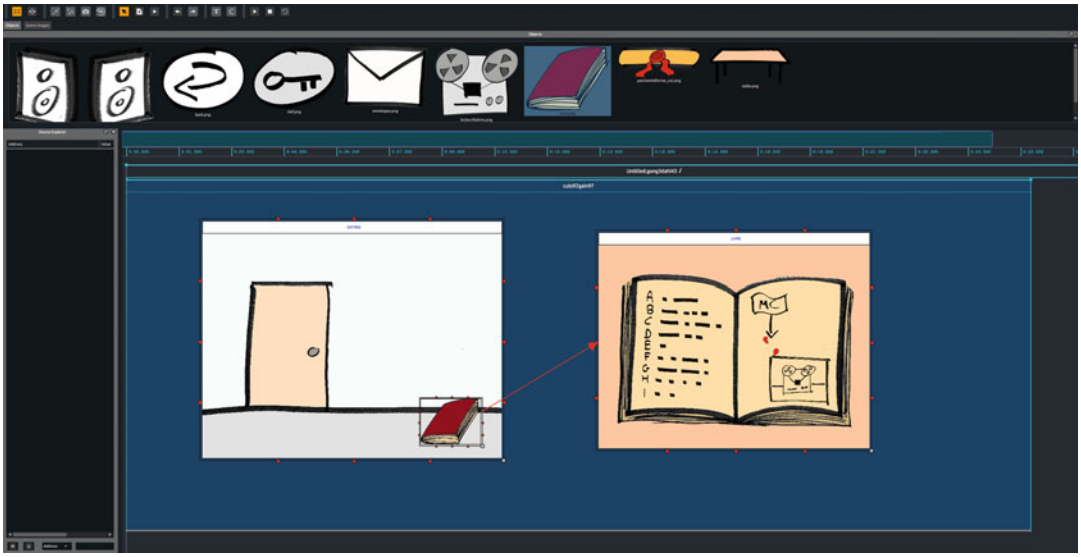
SEGMent was originally designed as a proof of concept. The SEGMent-engine is implemented in Unity3D and can be launched on MacOSX, Windows, Linux, Android, and online (WebGL). The diagram editor is, for its part, based on *DIA Diagram Editor* (http://dia-installer.de/), where flow chart has been adapted for escape game-making properties. DIA is a perfect diagram drawing tool; however, it lacks the ability to easily add custom properties on state/transition objects, and hierarchy is not implemented for including an image (object) into another (scene). Editing a SEGMent scenario in DIA can be really cumbersome for a neophyte. Therefore, for a proof of concept, DIA has perfectly fulfilled its job, but the need to have a fine management of time, condition, and hierarchy forced to switch to another editor environment: i-score. This new engine is the main goal of SEGMent^2.

By using the plug-in management system included in i-score, it becomes possible to port all the above mention features of SEGMent within the i-score environment, thus taking advantage of the time, condition, and hierarchy possibilities offered by the system. As illustrated in Fig. 5, objects in scenes are now fully enclosed into them (hierarchically) and each element (scenes, objects, transitions, etc.) can have time and condition tied to it, as custom property. Furthermore, SEGMent being now in i-score means that it can be linked with other i-score plug-ins, and notably the ones about flexible time (useful in game scenario, where the player inputs condition the narrative unfolding) and about parameters automation. Finally, a SEGMent scenario can now be separated into several sublevel, easing the game and level designers tasks.

With SEGMent^2, it is now possible to say that i-score is not only a multimedia **conductor** but also a **master hand**, able to guide the scenarization of video games.

VMO-Score

Machine improvisation refers to artificially augmented musical performances where machines contribute creatively to the musical outcome. Musicians use machine analysis tools to generate a computer accompaniment from musical examples. This allows the computer to generate music in ways that preserve the style of the musical examples given to it without a need for



Timed Automata for Video Games and Interaction, Fig. 5 Screen capture displaying the SEGMent^2 plugin within i-score

programming. During performance, these generative mechanisms are either controlled in real-time by another operator or are programmed to interact according to readily prepared scenarios.

Variable Markov Oracle (VMO) (Wang and Dubnov 2015) is a machine improvisation method based on automatic analysis of the musical structure of a recording. A VMO is a data structure capable of identifying repeated subsequences within a multivariate time series. After symbolizing the time series, repetitive structures can be extracted and used for music improvisation.

Currently, interactive music pieces require separate phases of constructing generative models and structuring them into a larger compositional plan. In Arias et al. (2016), a new system is proposed in which the machine improvisation tools based on VMO is combined with i-score scores in order to control the improvisation according to larger structures found directly from a musical recording and real-time interactions defined by the user. This allows construction of improvisation scenarios in ways that (1) are organic with the musical materials used for generating the music and (2) interact with the performer/environment during the improvisation.

Conclusion

We showed that the interactive score system *i-score* is able to specify scenarios featuring time, conditions, and hierarchy, which are essentials for exhaustive interactive systems such as performing art and video-games. Moreover, we presented a formal model for i-score, showing that Timed Automata is a well-suited formalism for the modelling and verification of interactive systems where both logical and temporal constraints are needed for a rigorous interactive creation.

Definitions

Toxic behavior refers to actions that have a detrimental impact on other players in online games. Gray zone users exhibit behavior that falls between toxic and normal users. While technically permissible, unsportsmanlike behavior is a form of conduct that can negatively affect other players.

Introduction

Online gaming has become a popular leisure activity for individuals seeking refreshment and enjoyment. However, several factors within the virtual gaming world can impede this experience, including toxic behavior. The anonymity of cyberspace often makes it easier for individuals to engage in immoral actions compared to real-life interactions (Davenport 2002; Suler 2004). This type of behavior not only diminishes the satisfaction of other players but also harms the reputation of the game. As a result, game developers have implemented various measures to prevent toxic behavior. However, there is no universally accepted definition of toxic behavior (Canossa et al. 2021) and no definitive solution to addressing it (Adinolf and Turkay 2018). This entry aims to investigate toxic behavior by broadly defining it as any actions that cause psychological harm to other players or damage resources within online games.

Toxic behavior can be divided into two main categories based on the methods used to execute it: (1) *Outside of games*, utilizing tools or programming that exist outside the game world, and (2) *Inside of games*, utilizing only the functions available within the game world. Examples and key characteristics of each type of behavior are outlined in Table 1.

Initially, *Outside of games* alters the intended gameplay of the developers, thereby undermining the fairness of the game and ultimately damaging the game world (Han et al. 2022). Such actions are widely regarded as negative within the context of online games. These include the utilization of game bots to acquire an unfair advantage or using illegal programs to secure victories. Additionally, this category encompasses the modification or duplication of programs to establish private servers or to exploit hacking vulnerabilities. The primary motivation for these actions is often financial gain in the real world, and cheating is utilized to achieve success within the game.

On the other hand, some behaviors are not problematic from a mechanical perspective but problematic from a user's perspective. These actions, referred to as *Inside of games*, follow

Toxic Behaviors in Online Gaming, Table 1 Category of all toxic behaviors in online games

Division	Subdivision	Goal	Example
Outside of games	Using external tools	Money, win	Game bot, wall hack, aim bot . . .
	Modding	Money	Private server, server hacking . . .
Inside of games	Trolling, griefing	Fun, hate	Aiding the enemy, spamming . . .
	Unsportsmanlike behavior	Win	Cheap play, road block . . .

the rules set by the game world, but they offend other users and adversely affect the game world, such as causing players to leave. This is because online games are also a type of society. Trolling and griefing (Achterbosch et al. 2017) are prime examples and include intentionally losing and speaking rudely, etc.

Trollers or griefers, troublemakers, irritate other players only for their own amusement. The main reasons for trolling are psychological factors such as boredom, attention-seeking, and revenge (Shachaf and Hara 2010). Other similar behaviors include unsportsmanlike behavior, which is motivated by a desire to win and achieve more in battles. Detailed actions of unsportsmanlike behavior are described in Table 2.

Toxic Behaviors in Online Gaming, Table 2 Unsportsmanlike behaviors

Behavior type	Description
Break teamwork	Seeking only their own benefits
Roadlock	Hindering other players from moving forward
Offensive chatting	Blaming others, speaking sarcastically
Deliberate defeat	Intentionally losing games to profit a particular user's account
Cheap play	Repeating a certain play pattern for win
Overkill	Immoderately killing other players
Unintended use	Using the in-game environment to block other players' viewing, clicking, etc.
Using NPC	Dragging the monsters to damage other players

There are several approaches that can be taken to address malicious actions. One method of countering *Outside of games* is to install security solutions on client devices. These software programs monitor the device and block any abnormal behavior detected. However, it is important to verify that the security solution has not been tampered with, and there is a significant drawback that additional software installations can negatively impact the user experience.

As a result, this method of installing additional software on client devices is not widely used in practice (Woo and Kim 2012). Another approach is to utilize information generated within the game. This includes analyzing logs to identify and block users who are behaving abnormally. For instance, if a game bot is being used, it will exhibit regular patterns of behavior. Since the logs are collected from the server and analyzed, this method does not affect gameplay or cause inconvenience to users. Log analysis techniques can range from simple rule-based methods to more advanced techniques using machine learning or deep learning. Another countermeasure is to collect legal evidence and respond through legal means. Lastly, there is the option of implementing a reporting system for users (Kwak et al. 2015).

Since *Inside of games* involves human manipulation, the mechanical aspect is not a concern. Therefore, the only countermeasures available rely on reporting and analyzing data generated within the game. While detecting *Inside of games* is more challenging than *Outside of games*, it is possible to analyze patterns of problematic behavior in order to detect and prevent it in advance. However, defining the specific problematic behavior is a significant challenge. This is why gray zone users often exist, as it can be difficult to accurately identify and control toxic behavior within the game. Above all, when many users get penalties for toxic behavior, it can make users feel that their freedom is restricted and cause dissatisfaction, leading to negative consequences

Related Works

This section examines the motivations and characteristics of toxic users within the field of online game security. Furthermore, it explores studies on methods for detecting and preventing toxic behavior in these communities.

Consalvo (2009) provided an overview of the history of cheating within video games and highlighted the potential benefits that users may gain from engaging in such behavior in multiplayer games. Beres et al. (2021) acknowledged the complexity of defining toxic behavior within the gaming community and illustrated that both players and game developers are committed to preventing such behavior, yet players who are exposed to it tend to perpetuate it.

Methods implemented on client devices to safeguard users from toxic behavior in online games are presented. Lee et al. (2021) presented for analyzing the protected memory area and the process of hacking programs in real time on client devices in order to protect users from toxic behavior in online games. The method was found to have high accuracy in detecting users utilizing the memory injection technique. Jeon and Kim (2021) proposed a client-side game protection mechanism based on ARM TrustZone technology for mobile games. This method was found to have no significant impact on performance and effectively detect common cheating techniques used in mobile games.

Various studies employ a range of features to detect toxic behavior in online games through analysis of in-game data. Tao et al. (2020) proposed techniques for detecting malicious behavior in games using explainable artificial intelligence (XAI). They assert their proposed method is highly efficient and can provide evidence and rationale for detection. Lee et al. (2016) presented a method for detecting game bots using self-similarity and tested this method using a large dataset from a massively multiplayer online role-playing game (MMORPG). Blackburn and Kwak (2014) developed a machine learning approach to detect ambiguous toxic behavior based on data collected from the "Tribunal," a community forum where players discuss and judge toxic behavior in "League of Legends." Canossa et al. (2021) presented a method for classifying malicious behavior through machine learning using a dataset from the game "For Honor." They defined different types of malicious behavior, such as "offensive behavior" versus "unfair advantage," and "warned" versus "banned."

Research has been conducted on the transmission of harmful behavior in online games, showing that the online gaming world is similar to society and has many psychological elements.

Zuo et al. (2016) found that cheating is more likely to affect other players when it goes unpunished. Woo et al. (2018) used data from massively multiplayer online role-playing games (MMORPGs) to demonstrate the social contagion of toxic behaviors, such as using game bots in online games. The study recommends targeted monitoring and selective bans to maximize the effectiveness of banning actions.

Data-Driven Approach

The method of detecting toxic behavior through data analysis can be applied to various online game security problems. By vectorizing player patterns, various analysis techniques can be employed to identify specific behaviors of interest, thus eliminating the need for ongoing rule creation and error correction. Additionally, the reporting system, which is a post-processing method that handles actions after they have taken place, but this method can detect and proactively respond to toxic behavior before it becomes a problem.

Feature Engineering

The data must be vectorized to utilize data generated within the game. Vectorization refers to the process of representing information as a list in which an order is established. There are various methods of vectorization, and the method employed depends on the characteristics of the data. One-hot encoding is a common method used for vectorizing categorical data. Only the domain's relevant features may be extracted, processed, and employed for vectorization. The resulting vector is utilized for a variety of analysis tasks.

Classification Using Similarity

There are many ways to represent a player's play patterns as vectors and subsequently classify them. (1) Euclidean distance, (2) Jaccard similarity, (3) Pearson correlation coefficient, and (4) cosine similarity are the methods. These methods can be employed to compare behavioral similarities and detect similar behaviors. Typically, behavior in games is represented as time series data. Thus, similarities can be determined by dividing the data into time windows of a specific size. The effectiveness of the method can be optimized by adjusting the manner in which the time windows are divided and combined.

(1) Euclidean distance is the coordinates of two points p and q in multidimensional space, respectively, $p = (p_1, p_2, p_3, \ldots, p_n)$ and $q = (q_1, q_2, q_3, \ldots, q_n)$. It is a method of calculating the distance between two points. The Euclidean distance formula is as follows:

$$d = \sqrt{\sum_{i=1}^{n} (x_i - y_1)^2} \tag{1}$$

(2) Jaccard similarity is a method for determining the similarity between two sets, A and B, by calculating the ratio of their intersection to their union. The Jaccard similarity has a value between 0 and 1, with a value of 1 indicating that the sets are identical and a value of 0 indicating that the sets have no common elements. The formula for Jaccard similarity is as follows:

$$J(A,B) = \frac{|A \cap B|}{|A \cup B|} \tag{2}$$

(3) The Pearson correlation coefficient is a numerical value that represents the linear correlation between two variables, X and Y. It ranges from +1 to −1, with a value of +1 indicating a perfect positive linear correlation, 0 indicating no linear correlation, and −1 indicating a perfect negative linear correlation. The Pearson correlation coefficient is calculated by dividing the covariance of the two variables in the data by the product of their standard deviations. The formula for the Pearson correlation coefficient is as follows:

$$r = \frac{\sum_{i=1}^{n} (x_1 - \overline{x})(y_i - \overline{y})}{\sum_{i=1}^{n} (x_i - \overline{x})^2 (y_i - \overline{y})^2} \tag{3}$$

(4) Cosine similarity is a method that uses the cosine angle between two vectors to measure their

similarity. It ranges from −1 to 1, with a value of 1 indicating that the vectors point in the same direction, −1 indicating that they point in opposite directions, and 0 indicating that they are orthogonal. Cosine similarity only considers the direction of the vectors, regardless of their magnitude, making it suitable for representing play patterns that may vary in absolute value from game to game. The formula for cosine similarity is as follows:

$$\cos(x, y) = \frac{x \cdot y}{\|x\|\|y\|} \quad (4)$$

Clustering

Clustering is a machine learning technique that groups unlabeled data into distinct clusters or groups. This technique takes into account the characteristics of the data and aims to identify the central points that can represent each cluster. This method is useful for classifying users by their behavior in the game world. Typical clustering methods are as follows: (1) K-means clustering, (2) mean-shift clustering, (3) expectation-maximization (EM) clustering using Gaussian mixture models (GMM), (4) agglomerative hierarchical clustering, and (5) density-based spatial clustering of applications with noise (DBSCAN).

1. K-means clustering is a technique for identifying the closest point by selecting an initial random point and determining its centroid. The centroid is subsequently shifted to the mean of the selected point, and the process of selecting a point closer to the moving centroid is repeated.
2. Mean-shift clustering is an algorithm based on a sliding window to find a dense region of data points. It uses a circular sliding window of radius r centered on a specific point. Each step repeats the process of moving the window to find a region with a high density within radius r.
3. EM clustering using GMM addresses the limitations of traditional K-means clustering and offers increased flexibility. In situations where K-means clustering fails to effectively cluster data due to similar mean values, EM clustering using GMM assumes a Gaussian distribution for the data points. It employs the EM algorithm to determine the Gaussian parameters for each cluster.
4. Agglomerative hierarchical clustering has two categories: top-down and bottom-up. This method involves expressing the distance between data points in the form of a tree, which is then segmented into the desired number of clusters. The top-down approach begins by starting with a single cluster and dividing it into smaller clusters. In contrast, the bottom-up method starts with individual data points and merges them into one cluster.
5. DBSCAN is a clustering technique that utilizes the density information of the data. The algorithm performs clustering based on density and automatically determines the number of clusters, even for data sets with complex geometric distributions.

Conclusion

This entry has examined the issue of toxic behavior in online games and explored data-driven methods for its detection. While the presence of gray zone users in online games may not appear to be a significant problem, it is important to consider them to maintain a fair and clean gaming environment, as they can have negative effects on other players, such as causing offense and damaging reputation. By utilizing methods of user behavior analysis, it is possible to detect and prevent not only toxic behavior from *outside of games* but also that from *inside of games*. In order to obtain effective results, it is important to select an analysis method in consideration of the characteristics and context of the data.

Computing for smart toys

Definition

Toy computing is a recently developing concept which transcends the traditional toy into a new area of computer research using ubiquitous technologies. Toy computing incorporates the physical component of a traditional toy combined with networking and sensory capabilities of mobile devices.

Historical Background

Toys have been a part of human existence for thousands of years, across every culture, being uncovered from as far back as ancient Egyptian times. A toy is an item or product intended for learning or play, which can have various benefits to childhood development. Toys can have a variety of purposes including education, leisure, and socialization. As such a substantial part of the human development, toys have continued to

maintain a presence in the daily lives of billions of individuals of all ages. While primitive toys included rocks and pinecones, they soon progressed into dolls, stuffed animals, and trains. As new ideas continue to develop to reflect the era and culture, it becomes evident that the toy is a product which has evolved along with humankind. It has become a marketable product which has blossomed into a multibillion-dollar industry. Referring to the North American Product Classification System (NAPCS), toys are generally classified as electronic or nonelectronic. For example, the Tamagotchi, a handheld digital pet, is an example of an electronic toy, while dolls and stuffed toys are examples of nonelectronic toys. Electronic toys have gained popularity, consisting of electronic parts with embedded systems. In the past few decades, electronic toys such as Speak & Spell, Tamagotchi, and Furby had become popular. More recently, sensors and networking capabilities have introduced a variety of new possibilities for the toy industry. Toy companies have embraced modern technologies such as mobile devices into the design of their products, reshaping the concept of toys and education (LaMonica 2012) through mobile applications and augmented reality. Toys have evolved over the ages from simple dolls and cars to electronic toys and more recently have been integrating mobile technologies.

Current Scenario in Toy Computing

Toy computing is a recently developing concept which transcends the traditional toy into a new area of computer research using mobile technologies. A toy in this context can be effectively considered a computing device or peripheral. Toy computing is comprised of two main topics in computer science: physical computing and mobile services. Physical computing builds upon the traditional idea of the toy by bestowing it with potential embedded systems and sensory devices to create a more reactive and pervasive experience. Mobile devices act as the primary computing device and may also use sensors while hosting mobile applications and services which complement the physical device. Physical computing combined with mobile services can create an augmented reality environment for toy computing through which users can immerse themselves in the toy computing experience. Augmented reality is the result of overlaying virtual components which react to real-world triggers captured through cameras and/or other sensors. This is achieved through the combination of physical computing with mobile services. The toy may be endowed with sensory and/or networking capabilities, allowing for new opportunities for personalized services based on user preferences and environment. This introduces a service-oriented architecture (SOA) approach. One of the key concepts of this type of personalized services is contextual data. The application can gather data on the context of the user (e.g., time of day, location, weather) and provide personalized services based on this context data. Information security and privacy present unique challenges in toy computing, which introduces an increased risk with products exclusively marketed toward children, which have potential to collect large amounts of information through sensors and vocal interactions (Tang and Hung 2017). Toy manufacturers are increasingly incorporating emerging information technologies, such as services computing and virtualization technologies, into their toys in a bring your own device (BYOD) paradigm. BYOD is an emerging application distribution model that encourages players to use their own mobile devices such as smartphones and tablet computers to access various online and mobile services to interact with the toys and even other mobile devices. For example, Disney Dream Play is an interactive music toy that employs augmented reality technologies through a mobile app on a user's own device, providing the user with an enhanced experience as they interact with various Disney characters. In this context, toy computing is defined as a software development and distribution model based on services computing for mobile services in an autonomous environment, interacting with toys in compliance with not only the safety policy but also the new

cognitive measurement requirements in the BYOD paradigm. This new paradigm introduces a service-oriented architecture (SOA) approach in toy computing between the toys (service providers) and children (service requestors). Further to the SOA model, toy computing has also recently begun to utilize cloud technologies for features such as voice recognition, customized services, and storage for use with the toy applications. One example of this is the CogniToys Dino, which utilizes IBM Watson to provide answers to questions as well as age-appropriate games and learning activities. As embedded systems also continue to decrease in size and increase in processing capabilities, more functionality may be placed locally to the physical toy itself rather than externally. While other IoT devices within the home become more connected, the toys may interface with these as well, as suggested by the 2015 Google patent (US 2015/0138333 A1) where anthropomorphic characters such as toys act as interfaces for media devices within the home through social queues (Hung 2015).

Definitions

Tracking is a process to measure the camera's pose that needs to be aligned to the targeted pose estimation on real world. In handheld mobile AR, tracking technique has been facing its evolution from black and square markers detection, to feature tracking, and the topical is a motion tracking technique. Therefore, a comprehensive review in AR tracking techniques is provided particularly in handheld mobile AR including the recent motion tracking technique in sight.

Introduction

As agreed with Azuma (1997), the definition of augmented reality (AR) is consists of three main portions: (1) the fusion between real and virtual images, (2) running in real time, and (3) registered in three perspective world 3D (Azuma 1997; Krevelen and Poelman 2010; Mekni and Lemieux 2014). Recently, AR has been moving forward from desktop application to handheld mobile application. Handheld mobile AR interface

seems to be the main research area. Handheld mobile AR refers to handheld mobile video see-through AR that acted as magnifying glass that shows the real objects with an AR overlay that mostly based on existing consumer product such as mobile phones and PDAs (Krevelen and Poelman 2010; Mekni and Lemieux 2014; Möhring et al. 2004; Azuma et al. 2001). According to Schmalstieg and Wagner (2007), handheld mobile AR interfaces are more robust than head-mounted display (HMD) devices. AR gears such as HMD is not a new approach in AR where the user see-through the device's camera to observe the scene that enriched with virtual objects.

Nowadays, handheld mobile devices which are often referred to as mobile, tablets, or smartphones have been delivered to user with powerful processors, high-resolution cameras, and a range of sensors such as global positioning systems (GPS), accelerometers, and magnetometers (Kurkovsky et al. 2012). These components are appropriate to run AR system. The handheld mobile device is convenient to a personal use unlike other hardware and devices which may require users to carry or wear its special equipment. The AR application run in handheld mobile platform is portable and not constrained to any specialized area (Kurkovsky et al. 2012; De Sá and Churchill 2012). The demands for handheld mobile devices make it practical to enable AR technology to handheld users (Zhou et al. 2008) and so derive out different solutions to its components especially the tracking techniques for the registration process in handheld mobile AR. Consequently, in the rest of this entry, we first discuss each of the tracking technique implemented in handheld mobile AR presently. Next, we express the strengths and drawbacks of each technique theoretically and practically. Then, we summarized and compressed our comprehension through a table. We come to conclude in the last section.

Tracking Techniques in Handheld AR

Tracking technique is one of the fundamentals to enable AR technology (Zhou et al. 2008). It refers to the process that measures the rendering camera's pose that needs to be calibrated in order to report accurate pose estimates either using a physical video camera within an AR system or tracks a fiducial that is attached to an AR system (Kato and Billinghurst 1999; Grubert et al. 2017). AR is the technology that combines real and virtual objects in a single display. It overlays the virtual object into our real world in real time. There are three major AR requirements which are (1) tracking and registration (Bimber et al. 2005), (2) display technologies, and (3) real-time rendering. According to Höllerer and Feiner (2004), tracking techniques had been discussed under one of the main components of handheld mobile AR which is registration. Currently, there have two main categories of tracking technique: (1) marker-based and (2) markerless. Marker-based tracking always refers to existence of square marker with edge detection and registration of virtual content only valid when four vertices of a square marker are being identified (Mekni and Lemieux 2014; Schmalstieg and Wagner 2007; Yuan et al. 2005). On the other hand, markerless tracking refers to tracking techniques that are not based on artificial AR marker that has been created deliberately while using features that already existed in the real environment as AR marker such as painting book cover to register virtual contents. Recent natural feature such as human feature has been used as natural features for tracking purpose that is also known as marker hidden tracking techniques (Mekni and Lemieux 2014) that still need existence of real-world AR marker to register the virtual contents. However, markerless tracking also included motion tracking that uses the sensor such as gyroscope and accelerometer for tracking purpose; no prepared environments are required while virtual content is up to date based on the estimation from frame to frame (Mekni and Lemieux 2014; Schmalstieg and Wagner 2007).

Due to the trend of traditional AR to handheld mobile AR mostly implemented in mobile phones, the physical surrounding is represented on the screen by the live image of the back-face camera. Thus, spatial relation between the

physical surrounding represented by camera image and the on-screen contents is represented by displaying digital augmentation (Vincent et al. 2013); this information is typically gathered by a tracking system. The tracking system gathers information on the handheld mobile device's position and orientation and measures this information with respect to a model of the environment coordinate system (Kurkovsky et al. 2012). Failure of a tracking system may cause registration error that degrades user's AR experiences.

Generally, there have three types of tracking methods used in handheld mobile AR interface which are (1) marker tracking, (2) feature tracking, and (3) motion tracking. Both marker tracking and feature tracking are discussed in the following first two subsections. Motion tracking in handheld mobile AR on the other hand is the latest technology that is based on handheld mobile AR interface that tracks the tracking device's motion to register the 3D virtual contents and stated in the third subsection.

Marker Tracking Techniques

Marker tracking technique is a conventional tracking which refers to the method that a square marker of known dimensions is used to define the world coordinate system (WCS), and the camera extrinsic parameters, i.e., camera pose, are estimated using the four vertices of the marker to register the 3D contents (Yuan et al. 2005). At early stage, it refers to the square markers which are prominent in AR tracking technique (Zhang et al. 2002). In handheld mobile AR, the marker-based tracking is frequently being used. However, before AR, the usage of barcode (combination parallel line) and quick responsible (QR) code (two-dimensional barcode) as markers for vision-inertial tracking is widely explored. Since these types of markers are similar with the square, black and white AR marker thus have been reused in AR to correspond with AR tracking system. For example, Ruan and Jeong (2012) proposed to restructure QR code features stored as AR markers to develop an application in handheld smart device that can extend to many fields. Finder patterns (three position detection patterns) and alignment pattern which are the fixed information of a QR code are used for tracking purpose in order to register the virtual contents.

In the tracking process, detection of the marker is the first essential process. During the marker detection process, the camera first needs to be captured by the camera view and sent to the handheld mobile device's computational system. Algorithm is used to search through the video frame for any square marker pattern. Once a square marker is found and the image content embedded by the square shape which defined as finder pattern is matched and identified, calculation is computed both position of the marker and the pattern orientation relative with the camera and lastly the 3D content is drawn in the foreground of the captured video. Inertial tracking process is carried on against the movements of the background video causing the model to appear attached to the background (Fig. 1) (Coordinate Systems, ARToolKit Documentation, last accessed 2017/9/28). Figure 1 explains the basic principle on how the ARToolkit works from the camera and captures video of the real world and sends it to the computer firstly until the final output is shown back in the handheld mobile display; lastly, so when the user looks through the display, they see graphics overlaid on the real world. Examples of conventional tracking library are ARToolkit and ARToolkitPlus which extended from ARToolkit with ARTag, a fiducial marker system using digital techniques (Fiala 2005).

Feature Tracking Techniques

Feature tracking technique is one of the existing marker-based tracking techniques that are based on features such as points, lines, edges, or textures. In a feature-based tracking system, 2D features include geometrical primitives (points, segments, and circles) (Shi and Tomasi 1994), object contour (Isard and Blake 1996), region of interest (Hager 1998), texture (Bastos and Dias 2005), and edge (Kissling et al. 2012; Chen et al. 2016). In handheld mobile AR, the limitations of the processing power, when rendering virtual objects, require a lot of processing time. Thus, textured markers are used for handheld

mobile AR tracking purpose (Kissling et al. 2012). However, the direction of researches has moved from marker-based to markerless AR because of the existence of artificial markers in the real scene leads to the nonnatural perceptions (Pang et al. 2006; Kar et al. 2002). Nevertheless, the markerless tracking system that needs to track physical positions requires a powerful processor and computational system, yet at the moment, they are still too immature to be used in handheld mobile AR. Markerless AR refers to the artificial marker hidden techniques that track the natural features which are the parts existing in the real scene as natural markers (Comport et al. 2003; Souza et al. 2014).

Examples of feature recognition used in feature tracking process are shown in Fig. 2. Vuforia is one of the tracking software development kits (SDKs) that are based on feature tracking. Vuforia is supported with natural feature tracking (NFT) and texture tracking library after both libraries are released in handheld mobile AR.

Motion Tracking Techniques

Motion tracking in handheld mobile AR usually is using visual-inertial odometry to estimate where a device is relative to where it started. Standard visual odometry uses camera images to determine a change in position by looking at the relative position of different features in those images.

Visual-inertial supplements visual odometry with inertial motion sensors capable of tracking a device's rotation and acceleration (Roberto et al. 2016). When the camera movement tracks the 3D space, it will continuously retrieve the coordinates and recursively updates the information of its current. In this case, its constant values are cue in stable motion, while it can be deferred, freeze, and move forward and backward. Thus, this indication presents the technique and computes the camera movement not in real time (Wagner et al. 2005).

In handheld mobile AR, one of the objectives is to render the virtual object in a real-world context with its accurate posture (Filippeschi et al. 2017). In order to actualize, AR system needs to know the position of the user, and this can be achieved in motion tracking by determining the motion of handheld mobile device itself supported with inertial odometry captured through built-in sensors such as accelerometer and gyroscope (Fang et al. 2017) together with the camera images to determine a change in position called

visual-inertial odometry (Lima et al. 2010). Visual distinct feature detection in the captured camera image is used to compute its change in location. Examples of SDK for handheld AR that are based on motion tracking are Tango (Marder-Eppstein 2016), ARCore (ARCore Overview, last accessed 2017/9/29), and ARKit (Introducing ARKit, last accessed 2017/9/29) shown in Table 1. Apart from motion tracking, ARCore and ARKit are available to understand the real environment through

detecting horizontal surfaces or plane to register 3D content, while Tango required depth sensor to do so. Since the tracker motion had been used to estimate the 3D content's position and orientation without real-world AR marker, it can lead to a more reliable tracking process. Furthermore, mapping technique is utilized to estimate 3D content's position and orientation through localization of data set to retain more stable and smooth augmentation, while ARCore can manage larger mapping data set than ARKit.

In motion tracking system, the user needs to place the 3D virtual object to the real-world scene initially and adjust its vision projection based on user preferable perspective and the size of the 3D object she/he want to be displayed on screen through virtual camera. Smoothing tracking is then carried on supported by the inertial sensor to track the handheld mobile device's motion to update the perspective view of the 3D content. Though so, the 3D content rendered is not based on the real-world scene (Roberto et al. 2016; Filippeschi et al. 2017) but through the speculation on the device's motion. Real-time registration only occurs when the user placed the 3D virtual object to the real-world scene for the first time. None of continuous real-time tracking happens along the tracking process proved by the position and orientation deviations of the 3D virtual object that always happen in motion tracking system (Lima et al. 2010). Without the precise position, orientation and depth information for the 3D virtual content may downgrade the augmentation of the AR system.

Model-based tracking (Reitmayr and Drummond 2006) technique is another motion tracking solution for AR. In this approach, trackers will construct their models based on the lines or edges in the model. This technique has always been used for heritage conservation (Noh et al. 2009; Pivec and Kronberger 2016), for example, tracking a landmark by modeling it and saving it in the remote server to register virtual objects on a specific physical surrounding. Currently, this method has also been used for city planning purposes to ease the planning process through 3D modeling and reconstruct the buildings in the AR system (Santana et al. 2016). This approach requires a large use of memory, storage space, and the processing power of a handheld device to call out the 3D model store in the remote server and a long rendering time which is not generally used in handheld mobile AR.

Comparison of Different Tracking Techniques

The marker tracking and feature tracking techniques are both marker-based either artificial markers such as QR barcode marker or traditional square marker that used in marker tracking or natural markers such as texture marker that is represented by existing real-world features used in feature tracking. In both marker and feature tracking, position, orientation, and depth information for 3D virtual content can be captured through the calibration of the real-world marker tracked by the AR system mapped with the predefined attribute of the marker stored (Hager and Belhumeur 1998; Neumann and You 1999; Pressigout and Marchand 2006; Lima et al. 2012).

On the other hand, motion tracking techniques do not require the specific real-world marker to be tracked along the process. No artificial or natural

markers are required in motion tracking process. No calibration of depth/distance information is available without the existence of real-world-specific marker unless additional depth sensor is added such as infrared sensor (Vincent et al. 2013).

Without relying on the real-world marker, motion tracking system successfully comply coherence tracking to retain 3D content on its position and orientation that firstly is registered by estimating the virtual object position and orientation from the previous tracking device's motion that can reduce 3D content registration error unlike marker and feature tracking that require the real-world marker to be tracked consistently in real time to calibrate the position and orientation of 3D content in real world when marker is visible and within trackable range of view. Without real-world marker trackable, 3D content registration error may occur, and calibration is running consistently to register 3D content due to its real-time characteristic.

Based on the definitions of AR stated in several studies (Azuma 1997; Krevelen and Poelman 2010; Mekni and Lemieux 2014), it is clear that real-time rendering is one of the basic attributes of an AR system. In real-time system, response within specified time constraints, often referred to as "deadlines," is a must (Den-Ari 1990; Shin and Ramanathan 1994), while execution on certain tasks or process is needed to be completed within a regular interval. However, in motion tracking, the current position and orientation of virtual contents are estimated relative to where it started. A change in virtual content's position is simulated by looking at the relative position of different features in those images compared with the initial point. This characteristic supports the coherence tracking process which means its constant values are cue in stable motion, while it can be deferred, freeze, move forward, and backward that refer to non-real-time system (Ben-Ari 1990; Shin and Ramanathan 1994; Kejariwal and Orsini 2016) since these actions allow virtual contents to not update timely and disconnect with time constraints definitely offend the definition of AR system for real-time rendering and thus downgrade the augmentation. Oppositely, in marker and feature tracking, real-world markers are being used as the carrier to connect between real and virtual. 3D content is registered in real time with position, and orientation calibrated based on the tracking process through the connectivity on the real-world marker to provide realistic AR scene with high augmentation.

In motion tracking, since the changes in virtual content's position and orientation are simulated relatively to where it started though the estimation of the device's motion tracked by the inertial sensor to update the perspective view of the 3D content. Thus, there is no connectivity with the real world; the precision of the estimation through inertial sensor's information toward virtual content's appropriate position and orientation becomes a big question. Due to this issue, experiments had been made (Siltanen 2012), and the deviation of position and orientation of virtual object frequently occurred as stated in Siltanen (2012), while position deviations of virtual object registered happened every time it is updated based on motion tracking system. Unlike motion tracking, marker and feature tracking using the real-world marker in their tracking processes, 3D content position and orientation are calibrated synchronous each time marker being tracked therefore can register 3D content correctly without any deviation.

Practically, AR technology has been studied to be implemented in supporting several important sectors such as medical (Thomas 2016) and retail industries (Siltanen and Aikala 2012) assisting serious tasks such as surgery, training, and merchandising. These industries treat the accuracy and precision as the most important elements (Trevisan et al. 2008; Ponce et al. 2016). Without the connectivity with the real world (Vincent et al. 2013), motion tracking fails to provide precise information such as position, orientation, depth, and size information of the 3D virtual content that is important for those purposes. For example, in retail industries, AR technology is used to display retailed products in 3D virtual form to ease the potential client that may be interested on the

product but cannot reach the physical sales platform in trying the product through augmentation; thus, the size of the product and its depth in the real world are very important for the precise odometry and size estimation. In marker and feature tracking, depth information can be calibrated precisely through the real-world-specific marker. Meanwhile, the size of the virtual object can be pre-defined by mapping with the real-world marker. By standardizing the size of the marker, virtual object representing the real-world product can be drawn accurately retaining the same size; it should be in the real environments unlike the motion tracking system, and there is no connectivity with the real world and the system understanding the real-world environment by detecting flat surfaces existed in the real scene although the surface detected may be in the different size. Without the specification of the real-world planar, the size of the virtual object cannot be identified and thus impossible to provide the precise volume information (Roberto et al. 2016; Marder-Eppstein 2016).

After reviewing several aspects between marker tracking, feature tracking, and motion tracking, Table 2 shows the summary of the discussion above.

Conclusion

In conclusion, conventional tracking technique, feature tracking technique, and motion tracking technique have been reviewed in detail. Each technique has been discussed including its functionality such as its strengths and drawbacks. The comprehensive discussion is summarized into a table to provide a more obvious confrontation.

Conventional tracking still is widely used in AR system for different purposes. Its stability leads AR to be used in more serious industries. However, the naturality of this tracking technique needs to be improved to enhance user's AR experiences. Feature tracking uses the real-world features as marker to register virtual contents, it is more natural compared with conventional tracking, and the potential to be practiced in various tasks and industries as well as its stability makes it the most attentive tracking technique. Most of the researches related with tracking techniques are based on feature tracking. Motion tracking is a new trend after the release of Tango, an SDK of AR technology for handheld mobile device. Motion tracking technique provides a smooth tracking process in order to enhance user's AR experiences. Even so, without the connectivity with the real world, it is hard to be implemented for serious purpose except for entertainment. Furthermore, partial real-time tracking offends the AR definition where real-time attribute is part of AR and thus downgrades the augmentation.

Further researches are needed focus on the fundamental issues in tracking. Providing

smoothing tracking with less registration error and solving the occlusion problem still is the challenging issue in AR. In realize the seamless connection among virtual and real; still have a long journey need to be move on.

Definition

Spatial visualization was defined by McGee (1979) as "the ability to mentally rotate, manipulate, and twist two- and three-dimensional stimulus objects" (p. 896). Although, better visualization skills can be achieved through childhood education and skill training, researches show it is still possible to train spatial visualization skills with various types of exercises in adults. It is not a new idea to use educational games and computer software in the education and teaching of spatial skills (Wells 2003; Uttal et al. 2013; Anderson et al. 2003; Kaufmann et al. 2000). Researches show it is possible to use VR/AR platforms to improve visualization skills. VR/AR platforms are a part of digital media, and special applications which focuses on the instruction of the visualizations skills can be developed with the support of the features and attributes of this media. Current best practices show learning by doing and constructivist methodologies fits well with this platform (Edutrends 2018). Students' motivation to the instructional activities can be increased due to the rich features of the VR/AR learning environment which can lead to longer instruction times, higher frequencies of instructional sessions, increased self-confidence due to increased number of instructional scenarios experienced by the learner.

Introduction

Educators are mostly spending effort to improve performance on STEM disciplines. Increasing need to professionals who are educated in STEM fields is the driving force of this strategy. However, basic skills such as spatial visualization which is an essential skill to improve understanding and success in STEM fields seem to be neglected. There are supporting evidence that show better visualization skills can lead to a decrease in engineering dropouts and an increase in academic success. On one hand, research studies show spatial skill can be improved with a lot of different methods dramatically; on the other hand, VR/AR platforms are gaining importance in instruction and gaming fields. Therefore, in this article, the questions how spatial visualization skills can be improved with VR/AR applications, what are the basic concepts of the particular subject, and what empirical evidence comes from the current research studies will be answered.

In this article, first, several definitions and the components of the spatial visualization skills concept will be introduced. Second, main parameters, measuring methods and well-known tests to measure visualization skills, will be explained. Next, sex differences in spatial skills, one of the most well and frequently studied part of the visualization field will be under focus. Sex differences will be followed by improvability, malleability, or plasticity of visualization skills, which are under the specialty of instructional technology field, with an emphasis on the method – media debate, which is one of the most important subjects of the instructional technology profession. Since, all VR/AR applications contain special software and hardware components, categories and instructional software and principles of multimedia learning will support the instructional frame of the subject. Finally, current pedagogical trends of the VR/AR instruction will be followed by the

research results focused on training spatial skills with VR/AR applications.

What Is Spatial Visualization

Starting from the first quarter of the twentieth century, spatial visualization field is a hot topic in cognitive psychology research, but there seems no real consensus on the definition of "spatial visualization skills" (Sorby et al. 1999). Spatial visualization was defined by MCGee (1979) as "the ability to mentally rotate, manipulate, and twist two- and three-dimensional stimulus objects" (p. 896). In Assessing Women in Engineering (AWE) Project, Visual Spatial Skills Overview (2005), spatial ability was highlighted as "... the over-arching concept that generally refers to skill in representing, transforming, generating, and recalling symbolic, nonlinguistic information" (p. 2). According to Kosslyn, visual imagery means to create mental images of how objects look in real world, and to be able to manipulate and change properties, orientation, rotation, and scale of these mental images in the mind (Kosslyn 1995). **Maria Kozhevnikov's mental imagery laboratory defines the same concept on their web page (** 2018**) as** "the ability to process visual information about spatial relations between objects or their parts and, perform mental spatial transformations and manipulations" (page id: 9 – Research). Most of the times, terms visual imagery, 3D skills, visualization, spatial recognition, spatial reasoning, and many more has been used interchangeably to define whole or at least some parts of the field. The words ability and skill has also been used widely and interchangeably, although former emphasizes that these properties are associated with genetic inheritance but latter emphasizes on positive training effects on improving the particular property.

Several researchers propose different schematizations to represent components of spatial visualization field.

According to Mental Imagery and Human-Computer Interaction Lab of National University of Singapore, Department of Psychology (2018), visualization ability can be examined under two main headings: (1) spatial visualization and (2) object visualization. Object visualization can be briefly defined as the process of visual information related to the pictorial appearances of objects and scenes such as plans, elevations, and sections (Mental Imagery Lab 2018). MCGee (1979) discusses about (1) spatial visualizations; (2)spatial orientations, the ability to follow directions with respect to a street map or a building plan; (3) spatial perception, to determine the spatial relations with respect to the orientation of viewers own body; (4) mathematical ability; and (5) mental rotations skills to rotate a two- or three-dimensional mental image with mental processes. AWE Visual Spatial Skills Overview (2005) and Linn and Petersen (1985) emphasize three main components of spatial skills: (1) mental rotation, (2) spatial perception, (3) spatial visualization.

The visualization skills can also be divided into three categories according to visual scales. The situation (1) in which the observer is larger than the object; (2) the environment is larger than the object and observer is surrounded by the environment; and (3) the observer and the environment are stationary, and environment is perceived as a stationary image of the same size or larger than the observer but as if located farther away from the observer (Hegarty and Montello 2006). According to the classification of Uttal et al. (2013), the spatial skills can be described as a matrix of 2×2 dimensions with reference to the target object as (1) intrinsic, relations between the parts of the same object, and (2) extrinsic, relations among objects in a group, and with reference to the environment and the observer as (a) static and (b) dynamic.

How Spatial Visualization Skills can Be Measured

There are many tests developed to measure different parameters of spatial visualization skills. Some of the well-known examples among these tests are mentioned in the following. Purdue Spatial Visualization Test (PSVT:R) was developed by Guay in Guay 1976. Pychometric properties of

this test were later studied by Maeda et al. (2013). PSVT:R is a mental rotations test and mainly used to investigate relations between the academic success of the engineering students and their spatial abilities. Another test to measure mental rotations ability is Vandenberg–Kuse Mental Rotations Test (Vandenberg and Kuse 1978) which was developed in 1978 based on Metzler and Shepard (1974) geometries and redrawn in 1995 by Peters et al. (1995). Embedded figures test investigates how surrounding environment effects the perception of a single figure embedded in the environment (Witkin et al. 1977). Different versions of paper folding tests has been frequently used in which the participant have to find the unfolded appearance of a folded piece of paper which was punched holes on its surface after being folded (French et al. 1963; Kyllonen et al. 1984). There are several other tests which measure the visualization abilities including mental cutting tests (Tsutsumi 2004) and box folding and unfolding tests, which have been frequently used and studied in related literature.

Sex Differences

Researches on the sex-related differences on spatial abilities and the reasons of these differences are still a hot topic on the spatial visualization field. According to previous studies, spatial skills vary from person to person. Researchers hypothesized about the reasons of this phenomenon as social factors, childhood games and toys, hormone levels, frequency and genre of frequently played video games (playing 3D games improves MR skills), sports activities, musical instrument playing skills, and sex differences (Meyer and Koehler 1990; Cherney and Coaller 2005; Cherney and London 2006; Hyde 2007).

Usually, male outperform female on spatial rotations tests with time pressure. Mostly male performs better on tests which were administered by using computers compared to paper pencil tests. Although in some areas of visualization there is no performance difference between sexes, strategies while solving spatial problems can be different (Uttal et al. 2013). Some researchers, on the other hand, claims sex differences in spatial visualization ability is very little or nonexistent (Linn and Petersen 1985).

McGee (1979) highlights four factors to explain the reason of sex differences in spatial abilities. These factors are (1) environmental, (2) genetic, (3) hormonal, and (4) neurological factors. The hormonal factors mentioned here are estrogen and androgen levels. McGee's study showed that high androgen hormone levels indicate low spatial ability levels in men. He emphasizes the balance between estrogen and androgen rather than the level of the single hormone. Another factor, also called neurological factor, is related to the development of brain hemispheres. Since synaptic stabilization of the brain lasts mostly in the first 15 years of life, better visualization skills can be achieved through childhood education and skill training during the first 15 years of the life (Rakic et al. 2009).

Training of Spatial Skills

It is understandable that neurological factors have a clear influence on the spatial visualization ability. The question is, is it possible to improve spatial skills by training? Research studies clearly indicate that visualization skills are improvable by training. In a meta-analysis, it was shown that "even a small amount of training can improve spatial reasoning in both males and females, and children and adults" (Uttal et al. 2013, p. 370).

According to Sorby's explanation (Sorby 2009), spatial skills are developed in three stages. First topological skills, which are primarily two-dimensional skills, are acquired. With this skill, children recognize an objects position and relation among other surrounding objects. Typically children who can do puzzles use this skill. Second, children acquire visualization skills of 3D objects. With these skills, children can visualize mentally a 3D objects view from different viewpoints and how it will look like if the object is rotated or moved in space. Last set of skills to be acquired are related with area, volume, distance, translation, and reflection concepts.

Since, it is very easy to train visualization skills with or without instructional software, solid training can be achieved by administering treatments which includes eye-to-hand coordination like sketching 3D objects on paper. These activities include playing with construction toys, playing 3D computer games, joining sports activities, and studying mathematics (Sorby 2009). These activities include "(1) playing with construction toys as a young child; (2) participating in classes such as shop, drafting, or mechanics as a middle school or secondary student; (3) playing 3-D computer games; (4) participating in some types of sports; and (5) having well-developed mathematical skills" (Sorby 2009, p.461).

Covering the same subject, Uttal explains that various training activities can help develop spatial visualization skills, so there is not only one best training activity. Instead training activities must be developed and selected depending on the instructional goal, amount of time, and availability of resources (Uttal et al. 2013).

Designing of Instructional Software

It is not a new idea to use educational games and computer software in the education and teaching of spatial thinking In architecture and engineering education, it is possible to see research studies about experimental software specially designed to develop spatial visualization skills some with immersive VR systems (Wells 2003; Anderson et al. 2003; Kaufmann et al. 2000).

VR and AR applications, which focus on the instruction of the visualizations skills, can basically be classified as instructional software. Human computer interaction (HCI) and interface ergonomy are some basic factors to be considered. VR–AR systems require learners to wear specially developed headsets. Especially while experiencing VR environment, some users complain about dizziness and nausea due to the inconsistent sensory data coming from the muscle system, eyes, and vestibular system. Software designers must pay attention to the movement, acceleration, orientation, and rotation speed of the user while moving in VR environment.

Any instructional software must follow a systematic approach based on the type of the skills and knowledge to be instructed. According to Roblyer and Doering (2010), an educational software can be designed in five different categories. These are (1) drill and practice software for skill development, which allows students to solve a large number of problems or to answer questions and receive feedback about the correctness of their answers; (2) tutorial software that aims to give an education on its own without the existence of a teacher. These include real educational material to be learned by the student. These are self-driven software and student can adjust the pace of the instruction to be delivered; (3) simulation software, technological models of a real system or environment which show how a system works. By using simulations, students can get a real-world experience. These software are focused on instructing about the system itself by allowing students to study on scenarios created procedurally by the software or manually by an instructor who observes the student during simulation process, rather than general problem-solving strategies; (4) instructional games that increase the motivation of the learners by adding gamification, game elements, rules, competition, and entertainment factors to the learning activity and simulations; (5) problem-solving software aiming at acquiring analytical thinking of the learner, in which the knowledge and skill are necessary for solving a certain problem.

As VR–AR software is also a part of multimedia learning, designers must know about the 12 basic principles of this learning method. Richard E. Mayer (2002) lists these 12 principles in his book as (1) coherence principle; (2) signaling principle; (3) redundancy principle; (4) spatial contiguity principle; (5) temporal contiguity principle; (6) segmenting principle; (7) pretraining principle; (8) modality principle; (9) multimedia principle; (10) personalization principle; (11) voice principle; and finally (12) image principle.

Method–Media Debate in Instructional Technology Field

Thinking of instructional methodology, all digital instructional systems including all instructional software, hardware, and mainly VR–AR systems, are a part of digital media. It must be discussed carefully that either digital media (VR–AR) or instructional method is the key element in training visualization skills.

One of the main discussions in the field of instructional technology is the method–media debate which was between Richard Clark and Robert Kozma and has been started in the early 1990s. According to Clark (1994), media has no influence on the learning and media is only a vehicle that delivers instruction to students. Media attributes (symbol systems like zooming into details, animations, highlighting details, etc.) are the surface features and the instructional method (learning by doing, project-based learning, etc.) chosen for the specific type of instruction is the main structural feature that influences learning. Clark claims "there is strong evidence that many very different media attributes accomplish the same learning goal" (p. 22). This means all media attributes are replaceable with some other attribute to achieve same learning gain, so media attributes are proxies of some variables of learning gain (Clark 1994).

Clark (1994) links the debate to various cost-effectiveness levels of various media. He claims an instructional designer must choose the less-expensive and cognitively efficient (easy to learn, fast, and permanent instruction) way to deliver decided instructional method. Therefore, a designer must be aware of certain media attributes which can be more effective, efficient, and easier for various learners and tasks.

Pedagogical Trends and Benefits of VR/AR in Instruction

AR and VR technologies can be used as the media to deliver traditional instructional methodologies. Students' motivation to the instructional activities can be increased due to the rich features of the learning environment (Edutrends 2018). This kind of a learning environment allows learners to interact with the immersive environment and the virtual objects in the simulations, and actively manipulate the virtual surrounding to study on possible solutions of the problems which are a part of the immersive learning experience rather than passively listen or watch the instructional content. Therefore, best instructional practices experienced with the VR/AR media are based on the constructivist instructional approach applied with learning by doing methodology (Edutrends 2018).

As it was reported in Edutrends (2018), some of the outstanding pedagogical trends of VR/AR instruction are: (1) conventional educational material which are being converted to digital educational materials to be used with VR/AR; (2) using the instructional capacity of games by creating gamified instructional material, as "[...] experimental studies indicate that playing computer games engage the dopaminergic brain reward circuit, [...] the rewards that we get from computer games are not any less real at the neurobiological level" (Balkaya and Catak 2016, p. 28); (3) VR/AR environments make it possible for learners to experience lifelike simulations, learning scenarios can be created based on experiment-based learning strategies; (4) by using the advantages of wireless internet connection almost anywhere on the world, learners can decide whenever and wherever they want or need to be trained; (5) instead of a learning experience without the existence and feedback of an expert observer, blended learning, which is supported with immediate presence and mentoring of an expert observer or teacher is suggested; (6) with easy-to-use developing tools, even learners can design and create their own learning experiences.

Although it is very early to talk about the existence of solid learning benefits of VR/AR media, Edutrends (2018) reports that six benefits seemed to be frequently presented in the current literature. These are; (1) VR/AR systems can stimulate attention more as they sends more sensory input, but this can also lead to a caution that too much stimulation can create an overload and reduce the attention; (2) immersive environments

seem to have positive effects of long-term remembrance of learned materials due to the fact that they allow the learner to live the experience in the context, which can lead to a better memorization of the learned material; (3) efficient learning pace, which learner can adjust the learning pace for her capacity; (4) immersive environments make it possible for learners to live in the simulations so that learners can participate in the learning experience rather than listening or watching the theoretic content; (5) research studies show VR/AR technology has a positive effect on motivation of learners; (6) VR/AR platforms, not different than some other existing digital learning platforms, presents the possibility of personalization of the learning experience by the learner, so that learner can adjust the activities, performance, and difficulty of the learning experience.

Training Spatial Visualization Skills with VR/AR: Evidence from Research

Very little or no systematic research work has been done to study the effects of VR/AR systems in training spatial visualization skills. There seem no commercial VR/AR applications developed to use for this training purpose either. Lightweight, cheap immersive VR/AR headsets were introduced in the middle of the second decade of 2000s. Probably, for this reason research teams have not been adopted these new technology headsets as research tools yet. In literature, mostly VR abbreviation means a VRML system running on a desktop computer equipped with 2D monitor. However, new technology lightweight VR/AR headsets can provide the immersion effect. Even with a newer technology, which is called mixed reality, user can walk through the virtual holograms which are floating in the real environment. So the participant can generate more precise sensory input coming from muscle, vision, and vestibular systems compared to the sitting experience of the VRML-like systems running on 2D computer screens. Only some research studies used active glasses to simulate the immersion effect. In some medical studies, immersive VR and mixed reality systems have been started to be used for training purposes of surgeons but these studies mostly are not targeting to measure the effects of spatial training with VR/AR devices. Neubauer et al. emphasize that "the well-documented sex difference in mental rotation favoring males has been shown to emerge only for 2-dimensional presentations of 3-dimensional objects, but not with actual 3-dimensional objects or with virtual reality presentations of 3-dimensional objects" (Neubauer et al. 2010, p. 2). Various studies show, studies made by video games (2D and nonimmersive 3D) can improve spatial skills, especially mental rotations, with training effect.

In a brain activity study researchers studied, in a pretest–training–posttest design, the combined effect of a training which lasted 2 weeks on mental rotations ability by using two-dimensional versus three-dimensional presentations of the Shepard–Metzler (Shepard and Metzler 1971) task. Research team assigned these 38 male and 39 female participants (age 15) and their accompanying cortical activation patterns assessed via EEG. They used active glasses to create a semi-immersive 3D effect. Research shows in 3D presentation of mental rotations task, reaction times of participants are shorter. With training, reaction times become even significantly shorter, and researchers witnessed no significant sex difference in reaction times. After analyzing scores, researchers found sex differences of males outperforming females in the 2D-presented version of mental rotation task, but not in the 3D-presented version. Additionally, they showed sex difference diminished after training. In neurophysiological sense, it seemed there is a decrease of brain activity after training for male participants, meaning increased efficiency in both 2D and 3D tasks, but for females this increase of efficiency is only in 3D mental rotation tasks (Neubauer et al. 2010).

In a study conducted in the engineering graphics field, researchers measured the improvement of spatial ability by using nonimmersive VR and AR instructional software. In this study, researchers planned to measure three parameters: spatial relations, spatial visualization, and spatial orientation. First two parameters were trained by

using the AR software and the last one trained with the nonimmersive VR software, which is actually a gamified simulation of a sport called orienteering. Control group got no instructional treatment. Measuring spatial orientation is not a very frequent practice. The researchers concluded that the training experiment shows the three components of spatial ability were improved significantly compared with the control group (González et al. 2017).

In an experiment conducted in architectural education field, participants said to reconstruct a volume by using plan and side views by using real or virtual cuboid objects in real-world, nonimmersive virtual environment, and immersive virtual environment. The result of the study shows although designers studied with 2D presentations of a 3D volume as the predominant medium to understand the spatial arrangement of cuboids, their 3D spatial understanding is improved with immersive VR instruction. In architecture field, immersive VR systems are mostly used for presentations. This study shows these tools, which can enhance perception and understanding of 3D volumes, can be used in the architectural design process (Schnabel and Kvan 2003).

In another study, a desktop VR (as VR also covers nonimmersive 3D desktop environments without a headset) environment is used. Researchers studied on 33 secondary school students grouped into three as interactive treatment group, animation treatment group, and control group. All groups trained on same exercise sets and interactive group studied with a software in which they can interact with the objects, animation group only watched the blow-up animations of the exercises, and finally control group studied with the classical pencil paper methods to train. Results show that all students showed some level of gain in all treatment groups. In more detail, male and female students of the interactive group showed the most improvement gain, animation group showed moderate gain and poor gain in conventional group. In general, male students achieved higher gains compared to female and sex difference in gain was the most in interactive treatment group. Female students, however, improved in all groups but less than males irrespective of the method used (Rafi et al. 2008).

In a study of a similar kind, three treatment groups were studied. First treatment group was trained with a nonimmersive desktop VRML application, second group used a desktop AR application, and last group used PDF3D application which has the ability to view 3D objects embedded in PDF files. Control group did not get any kind of training. All groups' participants used applications to view 3D objects from any viewpoint to understand the 3D geometry of the object without having the real object in their hands and sketch the workshop contour plan by hand. Results were measured by using a pretest posttest pattern. Results show all treatment groups show almost same level of significant improvement and control group has almost no improvement (Martin-Gutiérrez et al. 2013). This can be a result of the similar instructional methodology (sketching a 3D object on a paper by hand which was shown on a 2D monitor) in all groups although the media is different (VRML, AR, and PDF3D).

These examples show spatial abilities can be trained in both males and females with special training or with everyday activities. These effects, training durations, activities, and strategies can differ from person to person and among sexes, but it seems males benefit faster from the instruction and training especially in 2D mental rotations tasks. Immersive VR can be used to train spatial visualization skills of both sexes and it must be remembered that the training activity is the decisive element of the training thinking about the efficiency of the skill gain rather than the presentation mode (2D and 3D). Finally, mental performance of mental rotation tasks is dependent strongly to the representation mode among sexes.

Conclusion

In this article, essential information about improving visualization skills by using VR/AR platforms, and background information about related fields and evidence based on current research studies was covered. Since, it is very easy to

train visualization skills with or without instructional software, solid training can be achieved by administering treatments which includes eye-to-hand coordination. These activities include sketching 3D objects on paper, construction toys, playing 3D computer games, joining sports activities, and studying mathematics (Sorby 2009). VR/AR platforms are very convenient to develop applications which can include and simulate these kinds of activities due to their immersive nature. Evidence shows it is possible to improve visualization skills by using VR/AR platforms. However, designers ought to remember that VR/AR systems are a part of media and they merely deliver the instruction or drill which was designed by the instruction designer based on the selected instructional method. Therefore, the instructional method (not the platform or hardware) which was objectified as the application and delivered by the hardware is the main structure of any improvement in the visualization skills.

Transformational Games

Brooke Morrill and Sabrina Culyba
Schell Games, Pittsburgh, PA, USA

Synonyms

Educational games; Game-Based Learning (GBL); Games for health; Serious games

Definition

Transformational Games are games developed with the intention of changing players in a specific way that transfers outside of and persists beyond the game. These games can be digital, analog, or both.

Term Origin and Relation to Other Terms

The term "transformational game" was coined by Jesse Schell after his studio's work on a variety of games that were designed to transform the player in a positive way but did not quite fit within the popular "educational game" category (Schell 2013). Educational games (Gredler 1996), serious games (Wilkinson 2016), game-based learning (Plass et al. 2015), games for learning (Clark et al. 2013), etc., are all popular terms used to describe games that aim to positively impact the player. Schell's game studio, Schell Games, uses the term "transformational games" to describe their work on a wide range of projects designed to transform a variety of players in specific ways, including but not limited to:

- Educational Games: Typically refers to games used in a classroom context or to teach

concepts usually encountered in classroom contexts (e.g., Dragon Box by WeWantToKnow)
- Games for Health: Typically refers to games that support player health or health habits (e.g., Re-Mission by HopeLab)
- Impact Games/Social Good Games/Games for Change: Typically refers to games that promote player engagement in social issues (e.g., Phone Story by Molleindustria)
- Training Simulations: Typically refers to games which replicate real-world conditions and scenarios for player practice (e.g., HoloLAB Champions by Schell Games)
- Behavior Change Games: Typically refers to games which try to change player behavior and choices in the real world (e.g., SuperBetter by SuperBetter)
- Empathy Games: Typically refers to games which use narrative-driven experiences help players identify with an issue or group by evoking an emotional response (e.g., We are Chicago by Culture Shock Games)
- Citizen Science Games: Typically refers to games which allow players to contribute to real-world research or tasks (e.g., Foldit by University of Washington)
- Serious Games: Typically refers to games that tackle training or education in real-world industries such as defense, education, science, healthcare, engineering, etc. (e.g., At Risk by Kognito)

These terms often overlap with one another, partly because each carries with it specific connotations about the type of transformation it is designed to engender and/or the contexts in which it is applicable. The umbrella term of "transformational games" connects these different game types under their shared major attribute of targeting player change, regardless of context, topic, aesthetic, mechanics, or audience.

Broad Definition of Transformation

Transformational games deal with a wide range of potential impact on players and, therefore, are used in a variety of contexts. For example, transformational games intended for use in educational contexts (e.g., formal learning environments like classrooms) are often focused on changing a player's knowledge or skills for the purposes of improved academic performance, whereas transformational games intended for use in healthcare contexts are often focused on behavior or physical changes in players for the purpose of improved bodily or mental health. Still other transformational games that address social issues may target changing player beliefs or dispositions for the purpose of societal improvement. A nonexhaustive list of types of player transformation that transformational games can target includes the following (Culyba 2018, p. 90):

- Knowledge: The player knows something new (e.g., player can recall the meaning of vocabulary words)
- Skill: The player can do something new (e.g., player can solve algebraic equations)
- Physical: The player's body is changed (e.g., player has a lower resting heart rate)
- Disposition: The player's feelings are changed (e.g., player's feeling of stress is reduced)
- Experience: The player's personal anecdotes are changed (e.g., player has experienced what it's like to face discrimination)
- Behavior: The player acts in a new way (e.g., players choosing healthier foods to eat)
- Belief: The player's sense of truth is changed (e.g., increasing players' belief that human trafficking is a big problem worth tackling with urgency)
- Relationships: The player's social relationships are changed (e.g., getting players to have more trust in authority figures)
- Identity: The player's sense of self is changed (e.g., player starts to describe themselves as 'artistic')
- Society: The world around the player is changed (e.g., increasing overall voter turnout in a community)

Example Usage Patterns

Transformational games can be used in a wide variety of ways. Some typical contexts and play

patterns are as follows along with hypothetical illustrative examples. Not all games fit cleanly into one of the categories below, but this list provides a general overview.

- A game designed to introduce a concept for later discussion or to reinforce topics introduced by an instructor. Games used in this way are meant to be augmented with supporting materials outside of the game. For example, consider a narrative game developed for high school students that is meant to be integrated into a school health class. The game's storyline showcases several healthy and unhealthy relationship behaviors. After students play the game on their own, the class has a teacher-facilitated discussion about how to recognize and handle the sort of relationship issues illustrated during the game. The choices that students made in the game offer a tool to drive reflective discussion and debate.
- A standalone game designed to include built-in curriculum that provides overt instruction to the player. For example, consider a game that teaches about green building practices by directly instructing the player on these practices and tasking them to create virtual buildings with mechanics that model real-world construction materials and processes. The game provides feedback on the player's performance with more tips and information on environmentally friendly construction.
- An exploratory game that supports learning driven by player interactions rather than direct instruction. This type of game may still be based on curriculum but is likely less structured in the way it presents information to the player. For example, consider a fishing game that requires players to complete tasks related to fishing to progress through various levels. The game contents and mechanics are based on real-world fish and fishing practices, but the game does not provide up-front instructions to the player regarding which foods or techniques work for which fish. Instead, the player learns successful fishing strategies (and thus facts about real-world fish and fishing) through in-game experimentation, failure, and success.
- A "head-fake" game in which the transformational intent of the game is obscured from the player. For example, consider a game that advertises itself as an augmented reality treasure hunt in which players must catch ghosts floating around the city. The ghosts appear on sidewalks and begin moving when players get close to them, forcing players to run after them. Unbeknownst to players, the game was funded by an advocacy group for heart health as a campaign to encourage teens and adults to spend more time moving outside to improve their health.

Impact on Development

What distinguishes the development of transformational games from the development of traditional entertainment games is the emphasis on impacting the player outside the game. In traditional game development, the focus is primarily on game appeal (i.e., what draws players in) and player engagement (i.e., what sustains players' interaction with the game). Transformational game development adds an additional focus on the player's interaction with the world outside the game. As defined previously, transformational games attempt to create a specific change in players that transfers and persists to the players' interaction with the real world outside the game. "Transfer" here is the application of player change from the game experience to the real world (i.e., generalization), while "persistence" is the continued manifestation of the player change after the game experience is over (i.e., maintenance).

There are many examples of games initially intended only for entertainment that have been adapted for a transformative purpose. For example, Minecraft has been adapted to tackle many classroom topics. Transformational games are generally distinguished from these adapted games, though, because of the nature of their development processes (i.e., transformational game development includes intentional design to target a specific impact on players; see Culyba

2018 for additional detail). Specifically, transformational game development often includes:

- Additional considerations of the audience and context that the game must address (e.g., integration into classrooms)
- Establishment of transformational goals that express the impact the game aims to have on individual players (e.g., players reduce their smoking habits after playing the game)
- Analysis and design accommodations for barriers that impact player transformation (e.g., if players lack or need a refresher on some basic math skills which impede their learning more advanced topics, game developers can include in-game scaffolding for assisting players with those prerequisite skills)
- Inclusion of real-world domain concepts related to the game's topic (e.g., foreign-language vocabulary)
- Collaboration with subject-matter experts (e.g., a teacher or researcher who works professionally within the game's topic)
- Leveraging academic research as basis for the game's design (e.g., using research on the impact of peer accountability to design multiplayer features for a game to improve exercise adherence in players)
- Assessment of the game's efficacy (e.g., have players take a test before and after playing to measure the game's impact; see more below)
- Emphasis on feedback to player (or other stakeholder such as a teacher) about the player's transformation
- Consideration of funding through grants or nonprofit channels
- Accompanying supporting materials for use outside the game (e.g., documentation for teachers or debrief materials for players)

Assessment

The logical next step after designing and developing a transformational game is assessing the game's impact on player transformation. The simplest assessments (e.g., player self-reports of learning or behavior change) require few resources but only allow for anecdotal rather than causal evidence. More complex assessments (e.g., randomized controlled trials) require more resources but allow the developer to make causal claims about the game's effectiveness. In other words, the easier the assessment, the less conclusive the data, but the more difficult the assessment, the more conclusive the data.

Game development teams typically conduct informal assessments (i.e., playtests) throughout game development to obtain feedback on a variety of game characteristics (e.g., gameplay mechanics, usability of controls, likeability of characters, etc.). Conducting these playtests early and often is essential for creating an engaging experience for the target audience. In some cases, development teams can assess portions of the game or a mini-game experience that is part of the larger game for effectiveness during development, which allows the team to make changes to improve effectiveness prior to locking in game mechanics. This process can be more time- and resource-consuming than many development budgets can handle, though. More typically, formative testing (e.g., focus groups; Thompson et al. 2010; Hieftje et al. 2012) gathers input from essential audiences that developers incorporate into the game in order to increase the likelihood of transforming players as intended.

Post-development assessment teams typically conduct formal evaluations of the final product as it will be deployed to determine the extent to which player transformation occurs as related to gameplay. A rigorous experimental evaluation can answer many questions using a variety of methods (e.g., group designs [e.g., Mohan et al. 2017], single-subject designs [e.g., Joyner et al. 2017]) but can fit into two general categories: (1) did playing the game cause a player transformation? (e.g., Riconscente 2013) and (2) how does the transformation that the game caused compare to other interventions designed for the same purpose? (e.g., Castellar et al. 2015). Answers to both types of questions provide useful information, though the types of measures (and thus claims that can be made) vary widely based on the research methods used. The former

approach provides evidence that a game makes a change in a player, and the latter, comparative approach provides a more complete picture and justification for developing, implementing, and maintaining a game because of its comparative nature. If an objective evaluation shows that a transformational game not only achieves its goals but achieves them in a faster, more efficient, and more engaging way than the status quo, it may become easier to support widespread implementation and dissemination and subsequent resources for future projects.

Conclusion

The term "transformational game" encompasses the wide variety of descriptors for games designed with the purpose of changing the player in a meaningful way. Transformational games can be powerful tools for making many types of changes in many types of players, but developing and evaluating transformational games requires a large number of considerations.

Trustworthy Embodied Virtual Agents

Nathan Lloyd, Arsh Chowdhry and Peter R. Lewis
Ontario Tech University, Oshawa, ON, Canada

Synonyms

Embodied virtual agents, often abbreviated to EVAs, are computer-generated characters built to replicate the likeness of humans. The term is synonymous with 3D humans, virtual humans, embodied conversational agents, and digital avatars.

As a general descriptor for a collection of approaches, the term *ArtificialIntelligence*, commonly shortened to AI, is synonymous with various terms describing intelligent computers.

Trustworthy AI is a term used to describe Artificial Intelligence that is lawful, ethically adherent, and technologically robust. The idea is to provide AI systems with the capability to enhance and expose their trustworthiness toward humans.

Definitions

Despite the countless synonyms, *EVA*s are a general term for virtual human-like agents, with the various interchangeable synonyms utilized to describe some nuanced feature bestowed upon a virtual human, i.e., language understanding for conversational agents.

AI is an umbrella term for a collection of approaches that aim to distill intelligence within a machine. It encompasses specific approaches such as expert systems, machine learning, and deep learning.

Trust has many definitions, each tied to reasoning about *what* can and cannot be trusted. The decision perspective of trust can be defined as putting another in control of an uncertain outcome, thereby accepting risk given some context and predisposition to trusting others.

Embodied Virtual Agents

Embodied virtual agents (EVAs) are computer-generated characters built to emulate the behavior or appearance of humans and other beings. A term confusingly synonymous with many other terms (Lun 2011), EVAs are an umbrella descriptor for digital avatars, virtual humans, and virtual agents. However, using these alternative definitions commonly ascribes some nuanced feature or quality. Despite the difficulty in ascertaining concreteness with the many bundled descriptors, the lack of clarity infers the many applications and domains EVAs are deployed. The exact terminology

somewhat obfuscates the discussion, but the flexibility of the terms reflects the many techniques, problems, domains, and applications to which they are applied. For this article, the assumptions made when discussing EVAs will indicate the former, a virtual human-like agent. This distinction carries both a modern relevance and historical weight, with myth, history, and literature beguiled by the creation of artificial humanoids; Talos, Frankenstein's Monster, and Čapek's robots. While the desire to emulate human behavior and intelligence is one of antiquity, its realization (or at least partial realization) is a capability of modernity. Artificial intelligence has undoubtedly proliferated the application of EVAs across many domains. Whether deployed as new methods of HCI (Pustejovsky and Krishnaswamy 2021), conversational chat-bots (Traum 2008), or computer game characters (Lankes and Bernhaupt 2011), AI-assisted EVAs appear to be inescapable. W*hy is this?* Data availability, hardware advancements, funding, and hype have perpetuated Artificial Intelligence. Although many EVAs are developed symbolically, deep neural networks have facilitated a wave of features for EVAs to utilize. The most commonly discussed are the conversational agents that utilize Natural Language Processing (NLP), speech recognition, or rule-based responses, with many more incorporating subtle conversational elements under the umbrella of affective computing (Artificial Emotional Intelligence). EVAs have since adopted alternate methods of enhanced interaction, able to use non-verbal cues to identify gestures (Gris et al. 2015), to which they respond accordingly. This small sample of features highlights the difficulty in concretely defining an EVA, with many interchangeable interaction methods and countless overlaps across similar research, albeit without the distinction of a virtual human.

Trustworthy AI

Despite being an overloaded term, for the purposes of this report, *trust* will be defined as a mechanism to accomplish a goal between two or more parties in which the situation is underpinned by uncertainty and risk (Lewis and Marsh 2022); a definition grounded in the works of Gambetta (1990), Luhmann (1979), Marsh (1994), and McKnight and Chervany (1996). This distinction has been aptly expressed as a *cell membrane that protects. . . from outside forces by selectively letting in substances* (de Visser et al. 2012). Nevertheless, it remains a complicated term because of the many disciplines to discuss it. The digital world and the advent of cognitive agents have somewhat fragmented its understanding, with many unsure *what* can and cannot be trusted. As condensed by Lewis and Marsh (Lewis and Marsh 2022), four distinct perspectives can be ascertained; Accountability, Coordination, Goodwill, and Decision. The first two positions: Accountability, and Coordination, can be streamlined to conclude that only humans can be trusted. As Lewis and Marsh argued, Bryson (2018) sits within these perspectives, a proponent of the view that trustworthiness should not, or indeed cannot come from AI but from institutions and individuals. Next, the Goodwill perspective permits trust for sufficiently intelligent beings (including some AI), and finally, the Decision perspective establishes trust as a decision heuristic that applies to any object. As a decision heuristic, trust can be described as putting another in control of an uncertain outcome, thereby accepting risk given some context and predisposition to trusting others. Given its reliance upon situational context and personal predisposition, trust can be described as temporary or provisional (Dwyer 2011), specific to an individual (Dwyer et al. 2013). Trustworthy AI is not a new term, but recent developments like the EU's *Ethical Guidelines for Trustworthy AI* have forced the discussion to the forefront (2019). Despite its newfound popularity, it remains a complex and contentious area for discussion for AI. AI is itself contentious, often oversimplified, and commonly misunderstood. AI is a multifaceted umbrella term for a collection of techniques and approaches. So when one asks, "Do you trust AI?", how can another answer, given AI's many meanings and potential uses?

Evidentially, trust must be considered given the context to which it is applied. *For example, "do you trust AI to autocomplete your sentence?"* and "*do you trust AI to manage a nuclear arsenal?"* would undoubtedly involve two distinct sets of reasoning criteria for a trust decision. So why rely upon asinine questions about the totality of AI? The intent of these questions may appear benign. However, they demonstrate the desire of technologists to compel individuals into trusting AI (Ryan 2020). Examples of egregiously loaded language reinforce this belief (Enkel 2017), enabling trustworthy AI to become another buzzword for selling software. Gaining trust through similar means is defined as trust enforcement (Dwyer 2011). This distinction highlights how persuasion can convince another to make a decision they would not have otherwise. Conversely, trust empowerment provides an individual with the information to make trust decisions with no bells and whistles; it is about transparency, understanding, context, and the individual's predisposition to trust. Empowering trust decisions is integral for the intersection of AI and society, with the many horror stories of biased and inaccurate algorithms signifying their worth (Buolamwini and Gebru 2018; Cooper 2018). As the features embedded within EVAs become more advanced, endowing them with immense capability, the domain of trustworthy EVAs will undoubtedly become an increasingly prominent topic. The primary justification is that the features built to increase the acceptability of EVAs are naturally persuasive, such that the likeness of humans, the ability to gesture, and the capacity for conversation somewhat mirror the concerns of enforcement.

Trust Empowerment

A concrete definition of trust empowerment is enabling individuals to make informed decisions; it regards the delivery of data or information that humans can rely upon to make trust decisions (Marsh et al. 2020). EVAs can promote empowerment in various intuitive ways through their unique method of interaction with humans, able to draw upon state-of-the-art techniques to deliver said information. The EU's *Ethical Guidelines for Trustworthy AI* discuss the ethical imperative of explicability (2019, p.13), arguing that it is crucial for building and maintaining trust within AI systems. This imperative informs a proposed set of requirements for trustworthy AI, specifically identifying transparency and the mechanism of explainability for responsible and ethical AI. However, the development of complex black-box technologies impedes trust empowerment, a barrier to trust decisions to be made while informed. Explainability is proposed as a solution, but explanations commonly focus on informing AI experts. EVAs are suggested to bridge the gap between experts and laypeople, able to distribute knowledge in an accessible format. A recent study highlighted this approach (Weitz et al. 2019). The study compared two groups with identical information, one with purely graphical explanations and another with an additional virtual agent aid. Upon completion of the experiment, participants self-reported their trust in the system, finding a difference between the two groups with an increase in the group that experienced the virtual agent. The paper also supports the link between trust decisions and situational context, reflecting the abovementioned definitions of trust.

Is AI Fundamentally Deceptive?

A glaring issue about AI must first be addressed as a prelude to the discussion of trust enforcement for EVAs. Although this may be controversial to some, understanding the origin of AI as a method to replicate human intelligence naturally evokes the concept of deception. Under the European Union (EU)'s *Ethical Guidelines for Trustworthy AI* (2019), communication requires AI systems to inform users of their impending interaction with a machine. More explicitly, AI systems should refrain from representing themselves as humans to their end users. Although disembodied, Weizenbaum's ELIZA remains a prime example of this concern (Weizenbaum 1966), able to hold a

conversation and deceive humans into believing they are having a conversation with another human. ELIZA was noted as a "striking form of the Turing Test," which directly conflicts with the communication requirement. As a domain that prides itself in creating computers that *do the sort of things that minds do* (Boden 2016), an inherent deceptive quality is nested within its aims. The communication requirement may alleviate this concern by informing the end user, but whether this will matter as AI systems, and more explicitly EVAs, adopt the likeness, behavior, and abilities of humans remains to be determined. It is argued that the best customer experience is delivered when customers need help to tell whether they are conversing with a human or virtual agent (Hyken 2017); this does not bode confidence. It is too likely that stakeholders within the industry will be financially incentivized to develop virtual agents that are indistinguishable from their human counterparts, looking to maximize the technology's greatest value (Ammanath 2022). These examples elicit the concept of deception, which many agents, EVAs included, are often in conflict with, directly opposing the communication requirements.

Trust Enforcement

Trust enforcement overlaps with these deceptive processes, a general descriptor of methods that aim to convince, persuade, or outright force a trust decision (Marsh et al. 2020). Trust enforcement obfuscates the truth, and the many features that aim to improve the acceptability of EVAs often emulate human behavior, detracting from the available information. Substantial EVA research has focused on non-verbal characteristics, breathing patterns (Dar et al. 2019), face shapes (Ferstl and McDonnell 2018), and gestures (Kim et al. 2018), revealing how specific human features can be ascribed to agents to induce trustworthiness. These visual cues provide no discernable avenue for empowerment, undoubtedly employed by EVAs as persuasive techniques. Nevertheless, it could be perceived as unfair to ignore the benevolent aims for which these features are developed, most commonly in the name of improving the acceptance of EVAs. These persuasive techniques are by no means malicious by design. They can, however, be utilized to garner trust within risky contexts, accentuating the need for ethical consideration. As trust decisions are bound by their context, so will be the applicability of these features. Understanding the social effects induced by EVAs will undoubtedly prove to be difficult, but the discovery of these impacts is imperative considering the many unknown implications.

Concerns

Contemporary research highlights a paradox within trustworthy EVAs. Moradinezhad and Solovey (2021) discuss how EVAs have been preferred over their human counterparts or standard computer interfaces, spotlighting an unusual tradeoff between human-like behavior and trust. Their analysis reveals that agents without human behavior initially invoke more trust but that this trust is fragile and adversely impacted by failure and unreliability. On the other hand, agents who exhibit human qualities are initially perceived to be less trustworthy, but the trust endowed to these agents proves to be more resilient under failure. The authors suggest that this relationship may be due to individuals' expectations toward machines, holding EVAs to a lower standard. However, the human-like features may infer some standard of human nature, understanding that people make mistakes. This interpretation highlights enforcement's concern, including features to cloud an individual's judgment. This assertion may not be that simple. After all, enforcement is not solely about convincing but also about intent; perhaps the techniques that promote acceptability are permissible when enhanced by substantial empowerment. Of course, these considerations rely upon the context to which they are applied.

The willingness to trust various virtual agents over their human counterparts is a concern exacerbated by domains where sensitive information is disclosed. As discussed by Lloyd and Khuman (2022, p. 21–24), a variety of virtual agent-based

mental health services have increased in popularity, providing comfort for those who do not wish to utilize or have access to human-based therapy. EVAs have been similarly applied with success. Lucas et al.'s (Lucas et al. 2017) study found that virtual humans enable an increased rate of disclosure when compared to traditional therapy for military service members with PTSD. An individual's predisposition to trust EVAs with sensitive data is a cause for concern, with studies explicitly testing this relationship and highlighting a potential avenue for EVA exploitation (Lucas et al. 2014); EVAs that humans control. Again, this harks back to the communication requirement. Not only will it protect individuals from EVAs that sufficiently emulate humans to convince an individual they are, in fact, human, but it also inhibits adversaries from emulating EVAs. While these concerns extend far beyond EVAs, their human-like features only exacerbate them.

Conclusion

When discussing trust decisions, it is essential to recognize that there is no right or wrong choice (Dwyer et al. 2013); the factors that inform a trust decision are personal, situational, and often complex. To simplify these decisions, the developers of EVAs must strive for *trustworthiness*, empowering the end users in their trust decisions through transparency. Techniques that instill human features may work to cloud these decisions. This is not to suggest that such features do not provide some inherent quality that significantly benefits the end user. However, it is vital to be conscious of the outcomes, whether intended or not. Evidentially, a tradeoff exists between the affordances given to EVAs to promote acceptability and trust enforcement via deception. The EU's guidelines present an idealized view of AI, explicitly defining requirements to promote trustworthy systems. However, as much as frameworks, policies, and standards can deliver in promoting trustworthy AI, there is an even more outstanding obligation on the practitioners of EVAs to maintain these principles. Through careful adherence and consideration, practitioners should empower individuals to make their own trust decisions, accepting risk in situations they deem appropriate without the features that may otherwise convince and persuade.

Uncanny Valley in Virtual Reality

The effect of uncanny valley refers to a drop of emotional response to an artificial object. It is even higher in VR.

Introduction

Over the years computer graphics have been improved to be more and more realistic and developed special techniques to resemble various visual surface characteristics. Rendering virtual humanoid characters has been proven to be especially tricky, as humans tend to pay a lot more attention to their kind than to other beings or objects. The face is the most crucial aspect of the virtual character, as humans are extremely sensitive to deviations from a natural appearance (MacDorman et al. 2009). To create an emotional response to a virtual character, the anthropomorphism is a crucial factor. It could be assumed that the more similar a virtual character is to a human, the stronger the emotional response of familiarity.

But the effect of rising familiarity with rising realism of the virtual character changes at a certain level of similarity abruptly. At this point, the observer starts to feel alienated by the virtual character, and the emotional response becomes negative (Saygin et al. 2012). Only very high levels of realism can correct this effect again and show again an increasing familiarity (Misselhorn

2009). Originally the Japanese robotics professor Masahiro Mori found this effect and named it in Japanese, and later it was translated to uncanny valley (Mori 1970; Mori et al. 2012).

There are several explanations for these reactions. Most of them are related to human psychology and the high sensitivity for untypical behavior of other humans. Observing others, humans are building expectations about their expressions and subconsciously compare them to typical and assumed behavior. If assumption and observations are not matching, typically an emotion of aversion is shown, as the other is assessed as socially abnormal or psychologically ill. This sensitivity against minor deviations is also active in contact with virtual characters, when they reach a certain level of realism (Angelucci et al. 2014).

One theory is linking this reaction to the subconscious mate selection mechanism, which rules out not suitable mates and creates an aversion. Another theory links it to the avoidance of pathogens, which are associated with abnormal behavior.

Another theoretical approach is suspecting the causes in the cognitive conflict that is created by the doubt if a suspect is a human or a robot. This cognitive dissonance has also been linked to an assumed threat to the uniqueness of humans, as artificial creatures are getting more and more similar. As the virtual character is known to be not alive, they might also represent a threat to human observers of being a machine themselves. Also the not living acting alive has been described as a reminder of death (Ho et al. 2008).

The uncanny valley effect is known for physical as well as virtual humanoid characters, and it has been reproduced for robots as well as for rendered characters. In virtual reality (VR), it intensifies for several reasons. The newer generations of virtual reality headsets since the first released Oculus Rift DK1 in 2012 provide an immersive experience of being at a virtual place. This virtual world is completely surrounding the user, so there is no non-virtual world visible any more (Jones 2016). Compared to screen-based media like movies, experiences, and games, the conditions of perception change in VR. While on-screens there is always an outside and an inside visible, which creates a perceivable difference in visuality, this line is not perceived any more in VR. Characters, interactions, and the surrounding world are perceived more complete and compelling. Characters are shown in real human size and three dimensional (Gosh 2017).

Users of VR tend to examine the virtual world much more intense and pay a lot of attention to the details. This higher degree of attention creates the need to make VR applications far more detailed than regular screen-based experiences. The uncanny valley effect intensifies accordingly. Even virtual characters that would be considered to be so realistic that they passed the uncanny valley and create familiar reactions again in a screen-based media are likely to be still alienating in VR. This creates a need for even higher degrees of realism in VR or making virtual characters unrealistic on purpose to avoid the effect.

Besides virtual characters, also interactions in VR that try to resemble real-world interactions have been described to have this effect (White et al. 2007).

Examining the rise and design of the Kaizo subgenre of platformers, and whether it could work commercially.

Introduction

The platformer genre has been tried and tested for more than 30 years across multiple platforms, and while there have been many platformers released in the commercial market, there is a subset that remained hidden for a long time. Kaizo design takes platforming to the absolute highest of skill and has spawned a whole culture and development that has only grown in popularity.

What Is Kaizo

Kaizo's meaning in Japanese is defined as "reorganize, restructure, or reconstruct," but it has become the definition for the subgenre of platforming. Kaizo games are about incredibly difficult level designs; far beyond what would be in a commercial game.

The first example, at least reaching popular culture, would be *Kaizo Mario World* in 2007 (https://en.wikipedia.org/wiki/Kaizo_Mario_World). At the time, people described it as the hardest platformer ever made. The game was built off *Super Mario World*, and that detail is a major factor limiting the reach of Kaizo games that will be elaborated on in a minute. Nothing was added to Kaizo Mario World in terms of new assets, but the game used what was in the original release to design original levels.

That same year also had what would become the first original Kaizo game in the form of the *I Wanna Be the Guy* (https://kayin.itch.io/iwbtg) series.

I Wanna Be the Guy

I Wanna Be the Guy: The Movie: The Game like Super Kaizo World was the first time where these kinds of games broke into the mainstream. IWBTG was an entirely original design but used assets from other games for enemies, music, and obstacles.

Players had to go through challenging platforming levels where they could be killed at any time and sent back to the nearest checkpoint. The game embraced a kind of obstacle that has been dubbed a "Kaizo trap." Kaizo traps are obstacles hidden that the player would have no way of knowing about until it was too late, killing them and forcing the player to repeat the entire section

again. The only way to know where a Kaizo trap is located is to spring it.

The game had one official sequel with *I Wanna Be the Guy Gaiden* before the creator stepped away. Since then, modders and fans have been creating spinoffs of their very own, and there are too many to list here. What separates Kaizo games from the IWBTG titles is how they are developed.

Building a Kaizo Game

Kaizo games are technically illegal to play (https://www.nintendo.com/corp/legal.jsp#download_rom) and make because they are built off the ROM files of Mario games. ROM stands for "read only memory" and for the purposes in this entry represents the data that contains everything about the game. Of the Mario games, Super Mario World is now the most widely used as a foundation for Kaizo games, and there is a site that archives all the hacks made for it.

Since owning and/or manipulating someone else's ROM files is illegal, the author cannot provide exact names of programs or sites that host these files. Modders today have a dedicated "Mario World editor" program that they can use to create original levels and assets within the Super Mario World engine. For people who are used to Super Mario Maker, this other program is far more robust and allows modders to create elements that were never in the original game. This can go as far as having original music, mechanics, and new game systems.

Two of the most popular Kaizo hacks released in 2018 were "Invictus" and "Grand Poo World 2," both featuring original level designs and elements.

Once someone has finished their Kaizo game, they need to use one final program that allows them to create a "patched" version of the original ROM: replacing the respective files in the game with the modified ones. After that is done, the file can be run on emulators and could even be installed on a custom cartridge to be playable on the original platform.

Why Super Mario World

The most popular Kaizo hacks on the market are all built off the design and engine of the classic Mario games, with Super Mario World being the most popular now. The reason why Super Mario World has been the basis for so many hacks goes beyond just the name recognition.

From a design standpoint, the game is one of the best platformers of the classic era. It was one of the few titles to have two dedicated jump commands: Mario's normal jump and his "spin jump." Having two kinds of jumps added variety to the platforming and gave modders more ways of designing obstacles. As an example, modern Kaizo hacks have been allowing players to switch Mario's jump in mid-jump – requiring additional technical play.

Modders have thoroughly examined the engine of the game to discover bugs, advanced mechanics, and create elements that Nintendo would have never thought of. This also extends to the items, with designers creating new items for their Kaizo hacks or finding new ways of using the preexisting ones. The Kaizo hack "Fly me to the Stars" showcased and tested Mario's cape mechanics and physics beyond what Nintendo did.

The canvas of Super Mario World has been the main reason for its longevity in the Kaizo community.

Kaizo Design

Kaizo design is all about challenging the player's mastery of not only the original game, but to be prepared for anything. The first element of a Kaizo game is the difficulty – even Kaizo games that are rated as "easy" are still harder than any commercially released game.

Level design is meant to push the player to the highest levels of skill to get through them. Depending on the game in question, a Kaizo level can either be one demanding series of obstacles or be split into several sections.

A section is a collection of obstacles and hazards the player must get through before they reach a checkpoint that saves their progress. A Kaizo

section is built to be one continuous set of actions on the player's part; failure at any point will send the player back to the beginning of the section.

The hardest Kaizo levels will require pixel-precise play by the player to get through them. Taking things further, specific glitches (bugs that do not cause the game to crash) may be required by the player.

Two infamous obstacles featured in Kaizo games are "Kaizo blocks" and "Kaizo traps." A Kaizo block is an invisible block set purposely in what would be the easiest path to get through a section while making a jump. There is no way of knowing where a Kaizo block is until the player hits it and most likely dies. To avoid it, the player must purposely jump at an off angle that clears the block while still making the jump.

A Kaizo trap is setting up something to attack the player from either on or off screen with no warning. Usually, these traps are set up at the end of a difficult section as one final trick to catch the player. As with a Kaizo block, there is no way of knowing where a Kaizo trap is until it goes off – either killing the player or they avoid it. In Super Mario World hacks, many designers set up Kaizo traps just before the goalpost once the player thinks they are safe.

Kaizo design is explicitly set up around having one best way through the map. Unlike 3D design, you are not designing a Kaizo level around multiple solutions or paths. These levels not only test the technical skills of the player, but their ability to perform a precise set of actions from start to finish. Therefore, watching someone beat a Kaizo game looks very easy because they have done it enough times to build up the muscle memory and memorize the entire stage. There is no randomization in a Kaizo level: the same solution should work every time like clockwork.

This is achieved by using local timers. Each section of the level operates on its own cycle of animations and actions. Through this process, it allows the designer to know exactly what every element in the level is doing at any given time.

The mechanical nature of a Kaizo game also makes it the perfect candidate to watch Tool-Assisted-Speedruns or TAS (https://en.wikipedia.org/wiki/Tool-assisted_speedrun). A TAS is when an AI is programmed to play a game at a level of precision far beyond the abilities of a human player. These runs will often make use of frame perfect tricks and glitches that can only be performed by the computer.

The original Kaizo games following Kaizo Mario World did not make any quality of life updates to the game. That meant players could only save their games after a ghost house or boss, and they were limited on lives. As the community grew and Kaizo games became more popular, there has been a push to add more features to Kaizo games to make them less frustrating (but still difficult) to play.

Kaizo hacks today now give players infinite lives – removing any threat of game-overs – saving at any time on the world map, instant retries when they die, among other updates. Kaizo has grown thanks to modders learning from other games to incorporate new challenges or features into their designs.

From a cultural standpoint, more consumers have been exposed to it thanks to the rise of the Mario Maker and Speedrunner communities such as Awesome Games Done Quick (https://www.youtube.com/watch?v=GY0HnqnYMO8). With that said, the design of Kaizo does call into question whether it could work in a commercially released game.

Is Kaizo Marketable

Designing a Kaizo game is not the same as designing a game with the intent of selling. All the Kaizo hacks that are available would never be approved for sale at any digital store due to the as-for-mentioned modifying of a company's files. On one hand, that does leave room in the market for someone to try and make a commercial Kaizo game, but there are some issues there.

First, any game that tries to have a price tag will be immediately competing with the incalculable number of free Kaizo titles. The design would need to do something grander to justify the cost and stand out from those games. It would be easy to assume that just being a legal Kaizo game would be enough, but that is not the case here.

The major point about Kaizo design is how laser-focused it is in terms of the intended audience. There are three kinds of people interested in Kaizo games: players skilled enough to play them, modders who design them, and the audience who watches these games being played.

The first two groups often overlap, with high profile Kaizo players oftentimes designing Kaizo hacks as was the case with both Grand Poo World 2 and Invictus. Trying to convince them to buy a Kaizo game is going to be a tough sell, as they can just create their own or wait for their friends to design a new one. The sheer difficulty of playing a Kaizo game is why there are more people who watch runs as opposed to playing them, leaving them out of the potential consumer base for a Kaizo title.

There is the idea of making a "casual Kaizo" experience, but you once again run into problems with the market. As surprising as it sounds, there are Kaizo hacks designed for first timers to the genre. If someone is going to try and learn a Kaizo game, they will most likely go with the popular examples.

The hardest commercially released 2D platformer in 2018 was Celeste. The game's difficulty escalated over the course of three difficulty settings (two were hidden at the start of playing). The final difficulty required absolute precision on the player's part – reaching levels of Kaizo design. With that said, the developers implemented an assist mode to make sure anyone could finish the game (http://gameaccessibilityguidelines.com/celeste-assist-mode). Despite the difficulty of Celeste, the game was not marketed towards Kaizo players.

It is easy to assume that just because modders have used Super Mario World for so long that there's room to compete. However, from a design standpoint, trying to build a brand-new game with the explicit purpose to compete with the free Kaizo hacks would have the designer not only being compared to them but also indirectly competing with Super Mario World's design.

The power and scope of the tools being used has given modders complete freedom in designing levels and games. Another subgenre of the Kaizo community are "puzzle levels" – stages that take place in a single screen and require the player to figure out a specific solution.

Learning Kaizo

The best, and legal, way to examine and experience Kaizo design would be via Super Mario Maker 2 for the Nintendo Switch. Just like the first game, many Kaizo creators and players have taken to the game as the means of building levels and playing them.

While Super Mario Maker 2 lacks the functionality and depth of the created Kaizo tools, it is easier to learn and there are no worries of legal repercussions. Not only that, but the tool is the only way to make levels using the styles of Super Mario 3D World and New Super Mario Bros. The easiest way to find Kaizo-styled levels, for the most part, is to search for the hardest levels with the lowest completion by players.

For studying Kaizo games without having to play them, just searching for "Kaizo Speedruns" on YouTube should provide more than enough footage of popular streamers who have perfected these games.

Conclusion

The appeal and reach of Kaizo design and the community around it has crossed over to the mainstream. Even though it would be hard to compete directly with free Kaizo games, it does not exclude developers wanting to make commercial platformers on the harder side as evident by Celeste.

Given the growth of the community, the author expects to see further evolutions from Kaizo creators in the coming years. The only question that remains is if IP holders such as Nintendo will continue to allow them to exist underground, go after creators for infringing on their rights, or even allow them on the platform.

From a gameplay standpoint, Kaizo games represent the height of precision platforming design and are great at studying to see the

extremes of difficulty design, and the work that goes into playing them.

Underwater Enhanced Detail and Dehaze Technique (UEDD) for Underwater Image Enhancement

Definition

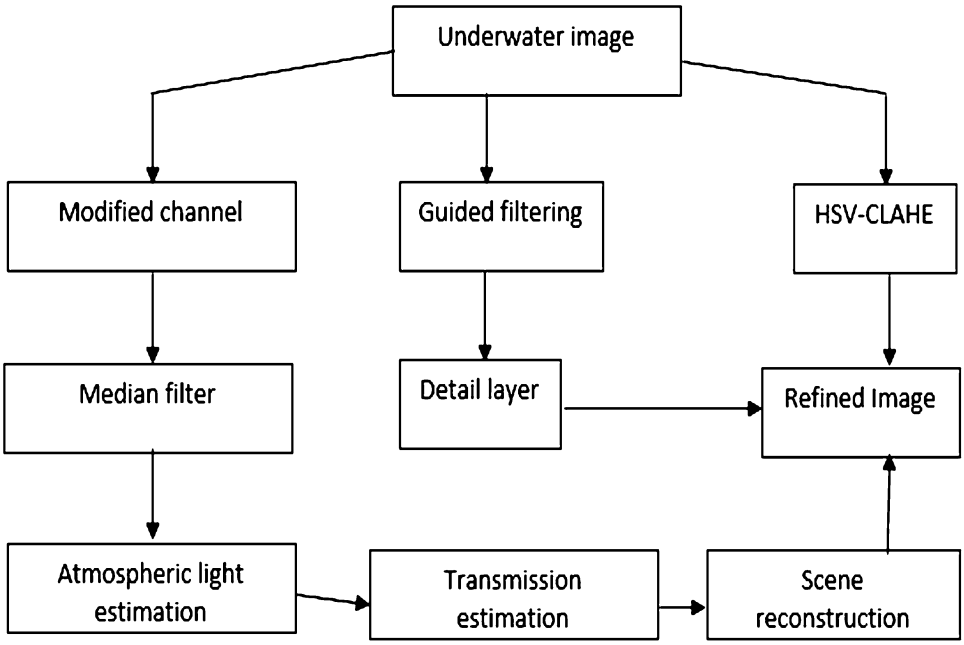
Underwater image enhancement is a process to improve the underwater image quality for further applications in several ways such as to recover image visibility, preserve details, reduce image noises, and improve contrast and color balance.

Introduction

Underwater images are often distorted due to two main reasons such as the light absorption and scattering. Water tends to absorb the red light (longest wavelength) compared to blue and green lights. Thus, the underwater images will become bluish or greenish appearance. Underwater images also suffered in limited range visibility, low contrast, and blurring due to the light scattering effects. Therefore, underwater image enhancement is needed to be carried to improve the underwater image quality, enhance image contrast, and restore the image visibility.

State-of-the-Art Work

The early attempt in recovering underwater image visibility was the polarization analysis method (Schechner and Karpel 2005) which can increase the image visibility range, improve the image contrast, and correct the image color. The dark channel prior (DCP) (He et al. 2009) was originally proposed to remove the light scattering effects on the haze image. Due to the promising results gained by the DCP method, DCP had been integrated with the unsupervised color correction method (Iqbal et al. 2010) in order to enhance the degraded underwater image and color contrast (Yang et al. 2011). Later, an underwater DCP method (Wen et al. 2013) had been introduced along with an underwater optical model to take account of the light absorbing effect of water. Besides that, Lu et al. (2013) had replaced the soft matting in DCP scheme with guided trigonometric bilateral filter (GTBF) to reduce the computational time and improve the image contrast using an automatic color equalization-based enhancement method. Besides that, another attempt in the underwater image enhancement was to carry out color correction on the red channel based on the Gray-World assumption and applied the DCP dehazing method on the blue-green channels (Li et al. 2016). As compared with histogram equalization, DCP method showed a better performance in improving the quality of underwater image (Sahtya et al. 2015). Red channel prior method (Borkar and Bonde 2016) applied the DCP on red channel only due to the reason that red channel usually go through maximum attenuation. A modified DCP method (Yao and Xiang 2018) was proposed to obtain attenuations of RGB channels separately and applied color correction for degraded underwater image.



Underwater Enhanced Detail and Dehaze Technique (UEDD) for Underwater Image Enhancement, Fig. 1 UEDD method

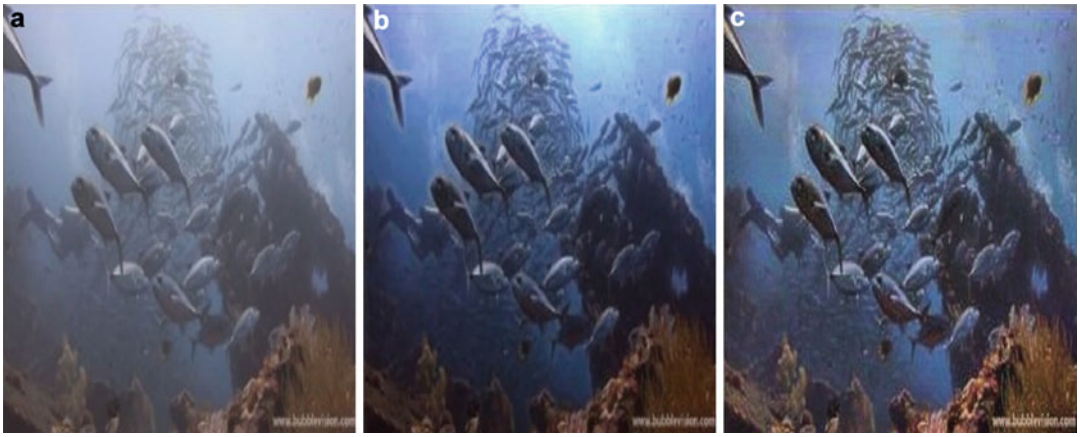
Some contrast enhancement methods such as contrast-limited adaptive histogram equalization (CLAHE) had been proposed for the underwater image enhancement. For instance, the Mixture CLAHE (Mix-CLAHE) (Hitam et al. 2013) enhances the underwater image visibility by combining the RGB-CLAHE and HSV-CLAHE. In addition, a comparative analysis (Wong et al. 2014) had proved the effectiveness of RGB-CLAHE and HSV-CLAHE in enhancing underwater image quality as compared with the contrast stretching and histogram equalization (HE). In addition, another underwater image enhancement had been proposed by fusing the CLAHE and unsharp mask (USM) (Zheng et al. 2016) to improve the underwater image quality.

Underwater Enhanced Detail and Dehaze Technique (UEDD)

Modified channel prior stated most images will contain many bright pixels and dark pixels, whereas the dark pixel and bright pixel indicate the pixels with lowest intensity and highest intensity respectively. Figure 1 showed the flow of the UEDD method. The algorithm of UEDD method is showed as follows:

The input image I^c will be a degraded RGB underwater image where c represents the RGB color channels. The UEDD method will compute the modified channels based on the modified channel prior and filtered by median filter as Eq. (1). The atmospheric light A is selected as the brightest pixel among the modified channels. After that, the UEDD method computes the transmission t as Eq. (2) where ω is a constant used to control the amount of descattering effect. The underwater image formation model is defined as Eq. (3) where J is the reconstructed underwater image. The image will then be reconstructed as Eq. (4) where t_0 indicates the lower boundary of the transmission.

$$\text{median}\left(\frac{\left(\min_c\left(I^c\right)+\max_c\left(I^c\right)\right)}{2}\right) \quad (1)$$



Underwater Enhanced Detail and Dehaze Technique (UEDD) for Underwater Image Enhancement, Fig. 2 Image 1 (**a**) Input (**b**) DCP (**c**) UEDD method

$$t = 1 - \omega \left(\frac{\text{median}\left(\frac{\left(\min_c (I^c) + \max_c (I^c) \right)}{2} \right)}{A} \right) \quad (2)$$

$$J = It + A(1 - t) \quad (3)$$

$$J = \frac{I - A}{\max(t, t_0)} + A \quad (4)$$

Meanwhile, the UEDD method computes the detail layer I_d as Eq. (5) as the digital image can be decomposed into the base layer and detail layer. The base layer I_s is the smoothed image of input underwater image that is produced by the guided image filtering. In the meantime, the HSV-CLAHE will be applied to the input degraded underwater image in order to enhance the color contrast. The UEDD method will then produce a refined underwater image I_f as Eq. (6) by combining the detail layer, reconstructed scene, J and HSV-CLAHE image I_{hsv} that is the input image after applied HSV-CLAHE and n is the scale of the detail layer.

$$I_d = I - I_s \quad (5)$$

$$I_f = \frac{J + I_{hsv}}{2} + nI_d \quad (6)$$

Figure 2 showed the result of image 1. From Fig. 2, UEDD method and DCP method can enhance the underwater image quality in terms of removing haze effects. However, the image recovered by DCP method was found to be darker than that of UEDD method. In terms of image details, the UEDD method also preserves more image details than the DCP method. From the recovered image of the UEDD method, the object edge is much clearer to be seen. The UEDD performed about 44.67% better than DCP in terms of the accuracy of recovered image contrast based on MSE test.

For sample image 2, the recovered image of the UEDD method can also see the object edge clearer as compared to the DCP method. Unlike the DCP method which produced an over-saturated image, UEDD method had produced a clear image that is natural looking. Figure 3 showed the results of DCP and UEDD on image 2. Based on the MSE test, UEDD had recovered the image contrast about 216.12% more accurate than the DCP.

From Fig. 4, UEDD method had improved the visibility of image 3 and recovered more image details. However, the images recovered by UEDD method for images 2 and 3 still have a

greenish appearance. This indicates the color correction need to be considered in the study. Figure 4 showed the results of DCP and UEDD on image 3.

The result for image 4 obtained by UEDD method had showed the ability to enhance the image details where we can observe the small fishes that are almost hidden in the image due to the similar color. However, the UEDD method cannot remove the bluish appearance. Figure 5 shows the results of DCP and UEDD on image 4. Based on MSE test, the image contrast recovered by UEDD is less accurate about 99.98% due to the high amount of image details.

Figure 6 shows the results of DCP and UEDD on image 5. From the Fig. 6, UEDD and DCP clearly managed to remove the haze effects. The level of detail obtained by UEDD method is higher and the image contrast recovered is about 9.9% less accurate as compared to DCP. Besides that, the recovered image of UEDD method looks more natural as compared with DCP method.

Mean Square Error (MSE) Test

The MSE test is a common test used to evaluate the accuracy of the recovered image contrast. The lower the MSE value obtained, the recovered image contrast is more accurate. Based on the MSE test, UEDD shows the image contrast recovered by the UEDD has more accuracy as the MSE value is averagely lower than the DCP method. UEDD computes higher MSE value due to the too many image details contained in sample image 4.

MSE test			
	DCP	UEDD	Percentage(%)
1	1427.63	986.819	−44.67
2	1691.87	535.199	−216.12
3	586.552	570.188	−2.87
4	0.207328	1681.18	99.98
5	610.971	678.139	9.9

Conclusion

In a nutshell, underwater enhanced detail and dehaze technique (UEDD) can improve the image quality in terms of visibility, removing haze effects, and preserving the image detail.

Definition

Software systems are digital products of development whose purposes vary.

Generally speaking, a problem is presented and a solution is proposed with programming and other techniques and practices. A modeling language is an, often graphical, way of describing the conceptual constructs of a software system. It shows the complexity and concepts of a system, similar to the functions of a blueprint. One such example is the Unified Modeling Language (UML) which is a modeling language used in software engineering that allows stakeholders to conceptualize and visualize a software system before, during, and after its development. UML uses diagrams, which are visual representations of anything that requires or could benefit from a visual representation. An example of a UML diagram is a class diagram. Class diagrams include what classes will exist in a software project, what member attributes and member functions each class will have, and how each class interacts with the other. These interactions can be function calls, inheritance, and implementation if a class extends an interface. Often software systems may need to consider accessibility, which is a set of rules and practices that target people with disabilities by enabling their participation in a given activity by easing their access to facilities, information, etc., and is often enforced by law in many countries. One such occasion that may require accessibility is sight loss. Sight loss can be from birth, developed, or accidental. It may affect visual acuity, the field of view, or both. Some cases require corrective devices, such as glasses, surgical intervention, or both. However, some cases may not be able to be treated. Some people with sight loss may use a method of reading and writing called Braille. Braille facilitates people with sight loss to communicate in writing. This brings people with sight loss closer to society; however, only a small percentage of people with sight loss know Braille. Educational games, or serious games, are games that are designed to teach a topic or skill. Their primary goal is to teach and they use gamification to do so. Blockbased programming is a form of programming language that uses small chunks of interactable code to connect together to create a program.

Introduction

With the popularity of the Unified Modeling Language (UML) in both industry and academia, it is important to remember that it is not designed for users of all abilities. Since UML is a visual modeling language, it proves to be difficult for people with sight loss to read and write. This entry describes Braille, a system of writing for people with sight loss. Additionally, it describes what UML is and how it works. Finally, it describes some applications of UML for people with sight loss.

Braille

Born in the early nineteenth century, Louis Braille was the creator of the writing and reading system that takes after his name. After a tragic accident at an early age, he lost sight in one eye. It is thought that after a couple of years, the other eye developed sympathetic ophthalmia, also losing its sight. His family, in which all members could write and read – an uncommon feat for the time – decided to send him to another city so he could study at a school for blind people. There, he started having contact with books for the blind which were written with the Roman alphabet letters in relief. This writing system was complex and ineffective due to the complexity of how Roman letters were fashioned. A new means of written communication was needed.

When the French revolution broke out, Charles Barbier de la Serre, a sighted military person, developed a writing system that was meant for secrecy and reading in poor lighting conditions. Barbier came up with a phonetic alphabet written as dots in relief on a paper. This idea was presented to the Institute for Blind Youth, where Louis Braille had his first contact with the proposed method. Despite being proven to be a better way for blind people to achieve written communication, Barbier was a sighted person and therefore could not understand the particularities and needs of those not sighted. Based on Barbier's proposal, Braille came up with the writing system used today and helps integrate people with sight loss into society (Jimenez et al. 2009).

Reports and surveys indicate that, in Canada, 1.5 million people identify as having sight loss, and more than 5.5 million have a condition that may lead to sight loss in the future (CNIB Foundation, retrieved on March 30, 2022). On the other hand, only a small percentage of this population knows how to read and write in Braille (Creedy et al. 2018).

Software Design and Software Design Practices

Designing software is a difficult task, especially when designing reusable software. Software designers and developers find this task easier because they have had previous experiences that allow them to foresee how they can break down objects into classes with precise granularity. Part of this experience is evidenced by the ability to recall what these professionals have done before, and apply that knowledge to the current project they are working on (Gamma et al. 1995).

Examples of design patterns include singleton, adapter, observer, and factory method patterns. Each of these has its own purpose in the software system. The singleton pattern, for instance, is often used when there is a need to have only one instance of a class alive in the system.

Software design patterns and modeling come together when the software product to be developed needs to be designed prior to its development. By understanding how to use these patterns, the software can be designed with diagrams that represent what and how the code should be written.

Unified Modeling Language (UML)

The Unified Modeling Language, or UML, was first adopted in 1997. It is a general purpose visual modeling language that is used to design, visualize, construct, document, and specify software systems; however, it is not a programming language (Rumbaugh et al. 1999). It is intended to be used at all levels of development and with all development methods. Although UML does not define its own standard practice, it is intended to be used in an iterative development process (Rumbaugh et al. 1999). UML is often used in many agile and scrum-based development environments.

UML is made up of several types of diagrams displaying various aspects of a software system. It was designed and grouped into several concept

areas. These areas include static structure, dynamic behavior, implementation constructs, model organization, and extensibility mechanisms (Rumbaugh et al. 1999). These concepts were used in the design of the language, as well as in how the models are built.

As previously mentioned, the Unified Modeling Language comprises many different views, including the static view, use case view, state machine view, activity view, interaction view, and model management view (Rumbaugh et al. 1999). These views are made up of diagrams that rely on visual aspects and symbols to better represent the aspects in the diagram. Some of the popular diagrams include use case diagrams, activity diagrams, and sequence diagrams. Each diagram works together to provide an overall view of the program, both with how the system should act and how users interact with it.

This system continues to be popular both in industry and within programming courses. It is considered a useful language to help design, implement, and understand specific software systems.

UML for People with Sight Loss

Representing UML diagrams for individuals with Sight Loss is a difficult challenge since UML diagrams are presented visually. This can be hard for Sight Loss programmers to understand the complexity of the software system as there are not many applications to portray the graphs to these individuals. UML is an advanced software design technique that may be challenging for visually impaired users when they transition from programming to understanding UML diagrams. While there are accessibility options in programs like Microsoft Visio for blind programmers, this can be challenging for a student that is trying to learn the concept as they are not sure how different software design concepts can come together in the diagram. This is important as it will severely limit blind programmers as they try to improve their skills and join the job market (Coburn and Owen 2014).

Researchers have developed UML tools for blind programmers so they can relay relationships between classes and state elements. In the first iteration created by Coburn and Owen (2014), they represented elements using combinations of push-pins, rubber bands, and sticky notes that included class details in Braille. The rubber bands were used to connect elements so they could be felt and followed by the user with their sense of touch. Specific relationships (i.e., nesting and generalization) can be created by a push-pin that shapes each element's relationships. While this approach was appropriate for the short term, the authors quickly discovered that there must be an application that can quickly interpret and create diagrams.

Audio Browser is the successor to Coburn and Owen's (2014) previous solution to allow blind programmers to develop UML diagrams. This application can interpret and present different diagrams by saying distinct names, attributes, operations, and associations using a computer voice-over that reads attributes to the user. Audio Browser allows the user to navigate the diagram using the up and down arrow key and read a set of frequent items called a tab group. The arrow key also allows the user to go to a list that may include nested classes, classes that the current class inherits, and classes that inherit the current class. An example of the application reading to the user is if the attribute is x: int = 0, it will be spoken as "x colon int initial zero." If there was any ambiguity/clarification needed for the user, the user can navigate the letter with the right and left arrow keys. For the blind programmer to understand the physical structure of the diagram, the program will read the placement of the class based on a certain spatial placement and pitch. For example, if the class was placed in the bottom left of the application, the user will hear it at a low pitch and on the left ear.

Educational Games

Educational games, also known as serious games, are educational tools that combine the aspects of

game play with a learning outcome of a topic. Alvarez and Djaouti suggest that educational games should include three important criteria: gameplay (the type of playful structure), purpose (the functions beyond the game aspect), and sector (the areas of applications covered) (Alvarez and Djaouti 2011). These games are often used in learning environments, such as classrooms, where they are used to improve learning experiences and can be used to create a laboratory-like environment that can help with increasing engagement and imagination (Abt 1987).

Within the domain of software engineering and computer science, these games are often completely digital and work to teach a wide variety of concepts, from computational thinking to parallel programming. Additionally, there are games developed for a wide variety of skill levels, ranging from primary school aged children to university classrooms.

Often times, these educational games use a concept called block-based programming to run the coding portions of games, especially for younger users. Blockbased programming uses a more puzzle-based approach, using a series of blocks that fit together to create a runnable program. Each block in a block-based programming language can be anywhere from a single variable to several lines of code, often condensing the program and reducing the amount a typing user may have to do. It uses a more visual approach to show the user where and how the blocks fit together and overall acts as a way to prevent syntax errors that are so common with novice programmers (Weintrop 2019).

With computer science education becoming so prevalent, there has been an increase in recent years in the number of computer science educational games that use block-based programming. Games such as Code.org and Blockly have become more common. Code.org uses block-based programming to encourage students in learning how to code. It uses puzzles involving pop culture characters, such as Frozen and Star Wars, to help increase the engagement (Code.org n.d.). The Blockly games are created by Google. Blockly uses its own version of a block-based programming to create a series of different games designed to encourage development. Blockly is designed to be open source to allow for changes to be made (Blockly Games n.d.).

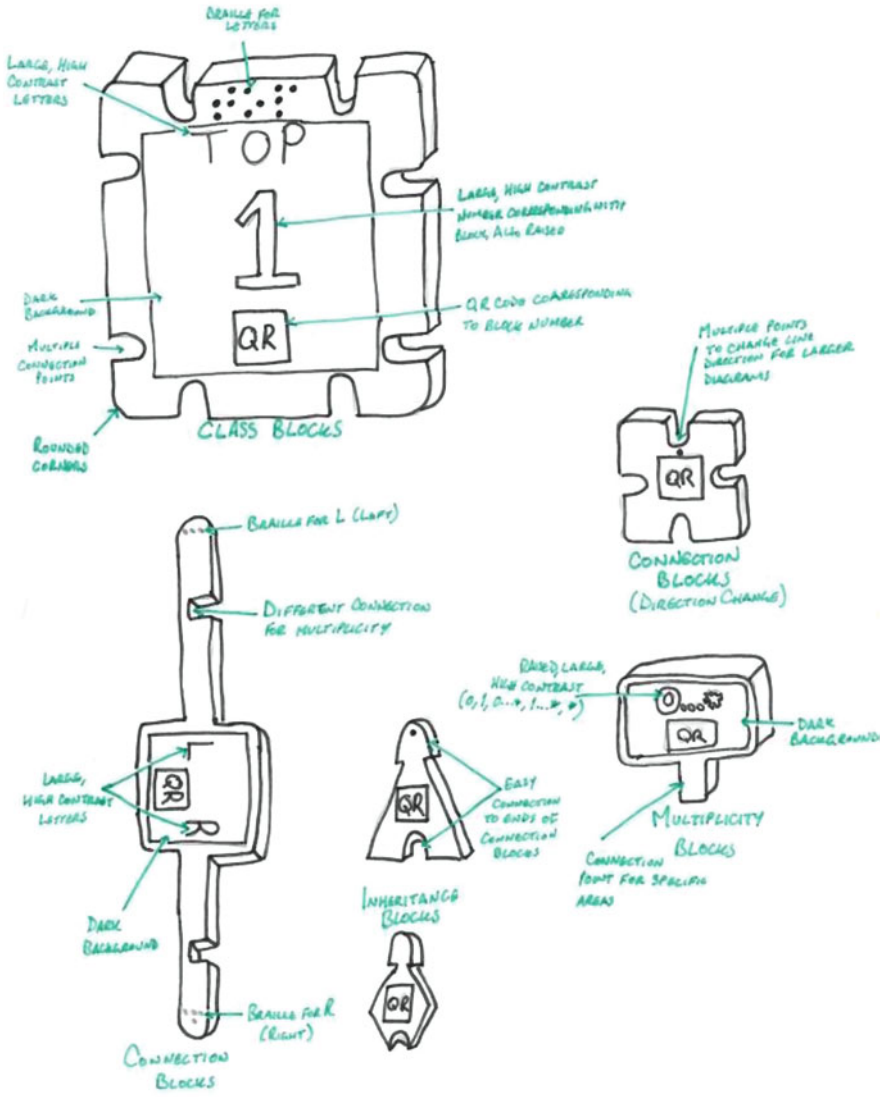
Although only two educational games were specifically mentioned, there are a wide variety developed and under development by both industry and researchers.

Creating UML Blocks for Sight Loss

One way to bridge the gap between UML and accessibility for people with sight loss is to create a series of physical blocks to represent the UML class diagrams. We have been working to develop a set of UML class diagram blocks, as seen in Fig. 1. This set will include several 3D printed blocks, including class blocks, connection blocks, inheritance blocks, multiplicity blocks, and more. The blocks are designed to include high-contrast identifiers, using white lettering on a dark blue background, and all of the letters and numbers are raised, to allow the user to feel the words. Similarly, the blocks include Braille labeling for those who can read Braille.

Each block uses shapes similar to the diagram. The class blocks are in a square shape to represent the class blocks in the diagram. Each of the class blocks has a different number to help the user to distinguish between each of the blocks when they build the diagram. Each of these numbers is raised. There are also Braille and English letters showing where the top of the block is, to help with organization. Finally, each of the class blocks includes 8 rounded-edge connection points, to allow for multiple connections between them. It also allows for as much flexibility as possible.

The connection blocks have 2 main pieces: a line connection block and a block to allow a change in direction. These blocks show how each block is connected and have multiple ways in which the lines can connect. The line connection block provides rounded edges that fit into the class blocks and the blocks that allow a change in direction. They can also fit into the inheritance blocks. The line connection block also includes a square connection point to allow the user to insert



Unified Modeling Language (UML) for Sight Loss, Fig. 1 A detailed design blueprint for the UML blocks

multiplicity. The connection points are designed to be different, allowing the user to feel the specific blocks that can be inserted into the corresponding slot.

There are two different blocks to show inheritance: an arrow and a diamond. The arrow is used to show inheritance, while the diamond is used to show aggregation, similarly to how they are used in the UML diagrams. These blocks also use rounded edges, allowing them to connect to the end of a connection block and fit into the class blocks. The inheritance blocks include a raised dot on the upper side to allow a user to feel which side should be facing upward.

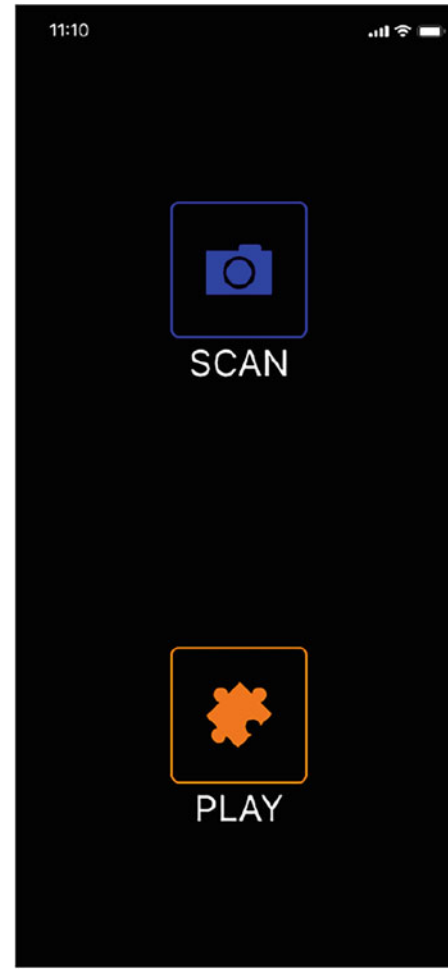
Finally, there are multiplicity blocks. These blocks include multiple types of multiplicity, such as zero-to-many, one-to-many, and more. These blocks use the square connection point and can be inserted on either end of the line connection points. The multiplicity shown on the

Unified Modeling Language (UML) for Sight Loss, Fig. 2 A paper prototype of the UML block diagram that will be placed on the 3d printed blocks

block is raised to allow someone to feel the letters and symbols.

Each block includes a QR code for easy access to the app. The QR code was chosen over computer vision to decrease the computational resources needed for computer vision. It was also chosen because, as long as the QR code is intact, the blocks can be cut out or slightly blurry in the pictures. Examples of paper prototypes of these blocks can be found in Fig. 2.

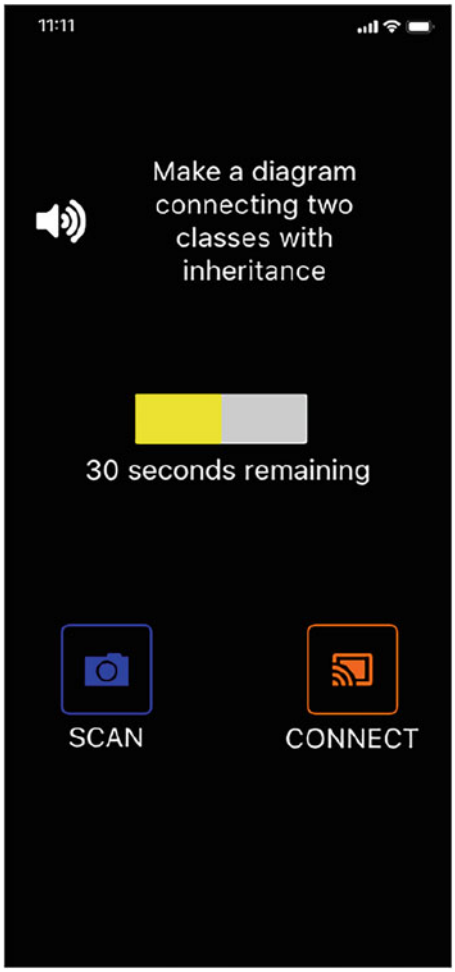
Once a UML class diagram is created using the blocks, the user will be able to take a picture using a mobile app. This app will include text-to-speech capabilities, as well as large, high-contrast buttons. The app will include only two buttons, as seen in Fig. 3. The first button allows the user to take a picture of the blocks. Once the picture has been taken, the app will decode the QR codes and provide audio and haptic feedback for each QR code that it finds. After hearing how many QR codes were found in the picture, the user will have the option to retake the photo, if it is missing QR codes, or send the QR codes to a computer application.



Unified Modeling Language (UML) for Sight Loss, Fig. 3 A mockup of the main screen of app

The computer application receives the QR code information from the mobile app and will use that information to create a visual representation of the graph. From here, the user will be able to use speech-to-text or keyboard input to fill out the information in each class. The user will also be able to hear what the graph looks like through a series of tones and text-to-speech.

However, if a novice to software design and UML wants to use the application to practice developing UML class diagrams, there will be an option to complete a series off challenges in the form of an educational game. The purpose of this game would be to help the user practice developing UML diagrams. This game would be



Unified Modeling Language (UML) for Sight Loss, Fig. 4 A mockup of the educational game portion of the app

developed to allow equal access for sighted people and people with sight loss.

To begin, the user would select the Play button, as seen in Fig. 3. This would take the user to the screen in Fig. 4. The game would include a series of sample questions, such as "Make a diagram that connects two classes using inheritance." This question would be read aloud, and the user would have the option to hear the question again using the large speaker button beside a written version of the question. The user would then be given a set amount of time to complete the challenge, which would be given visually in both a large progress bar and the exact time remaining in large print. Additionally, audio cues would be given for those with sight loss. Using spatial placement, a soft beeping would accompany the timer, showing where the progress is along the bar, with special reminders at half time and the thirty-second mark. When the user completes their UML diagram using the UML diagram blocks, they would press the Scan button. Once the diagram is scanned, the system would use the QR codes to determine the correctness of the solution. The student would then be able to connect the diagram to the computer application or move on to the next challenge. The user would have to complete a total of 5 random challenges of increasing difficulty and would be given a score and the total time. Each time they play, they would be encouraged to try to beat their previous score and time.

Conclusion and Discussion

These applications are important, as programming is a prominent part of our everyday lives and adding these applications will increase the accessibility of different software design techniques to blind programmers. However, while these applications are convenient, they require that the user is experienced/understands creating software. A future direction for learning UML diagrams for visually impaired student programmers is having a physical interactive block version of UML diagrams with Braille. This can be an excellent way to convey UML diagrams to sight loss individuals trying to learn the concept while being novices at programming. It also includes a game to help novices practice their UML diagram building skills.

Game engine: A game engine is a software framework designed to help developers create video games. A game engine typically includes a graphics engine, a physics engine, an audio engine, and other modules that handle game logic, artificial intelligence, networking, and other aspects of game development.

Game physics engine: A game physics engine is a software library or module that provides the tools and algorithms needed to simulate realistic physics in a video game. A physics engine typically includes a variety of tools and algorithms for simulating physical interactions between objects in the game world, such as rigid body dynamics, soft body dynamics, fluids, and cloth simulations. It also handles collision detection and resolution, which is essential for accurately simulating physical interactions between objects.

Introduction

Unity 3D is a cross-platform 3D computer graphics game engine developed by Unity Technologies. It is used to create 2D and 3D video games, as well as simulations and other interactive content for various platforms such as desktop computers, mobile devices, and virtual reality systems (Axon 2016).

Unity 3D provides a variety of features and tools for game developers, including a visual editor, scripting tools, physics simulation, audio management, and asset management. It supports a wide range of programming languages such as C#, JavaScript, and Boo. It can export to multiple platforms such as Windows, Mac, iOS, and Android.

Unity 3D is known for its ease of use and accessibility to both experienced and novice game developers, making it a popular choice for indie game development as well as large-scale commercial game projects. Its popularity is also

due to its ability to create high-quality graphics, realistic physics simulations, and advanced AI systems, which have made it a top choice for game developers (Dealessandri 2020).

Versions of Unity Game Engine

Unity is a popular game engine that has undergone numerous updates and revisions since its initial release in 2005. Here are the major versions of Unity that have been released:

1. Unity 1.0 (2005)
2. Unity 2.0 (2007)
3. Unity 3.0 (2010)
4. Unity 4.0 (2012)
5. Unity 5.0 (2014)
6. Unity 2017 (2017)
7. Unity 2018 (2018)
8. Unity 2019 (2019)
9. Unity 2020 (2020)
10. Unity 2021 (2021)

Each version of Unity has introduced new features and improvements, such as better graphics rendering, improved physics simulation, and enhanced scripting capabilities. Unity 5.0, for example, introduced physically based shading and improved lighting, while Unity 2019 introduced the Visual Effect Graph and High Definition Render Pipeline (HDRP).

Visual Effect Graph in Unity

The Visual Effect Graph is a feature in the Unity game engine (version 2018 and later) that allows developers to create complex and dynamic visual effects for their games. It is a node-based system that provides a visual interface for creating and manipulating particles, lights, textures, and other graphical elements that make up the visual effects.

The Visual Effect Graph allows developers to create effects that can react to user input, such as explosions that deform the environment, or effects that are triggered by certain game events. It also allows for advanced techniques such as motion blur, depth of field, and temporal anti-aliasing to be added to the game's visuals.

One of the key benefits of the Visual Effect Graph is that it allows for real-time editing and iteration, meaning that developers can see the results of their changes immediately without having to wait for long build times. It also supports GPU instancing and other performance optimization techniques, allowing for complex visual effects to be rendered efficiently.

Unity Game Engine in Hollywood Filmmaking

Unity game engine has been used in several Hollywood films for previsualization, special effects, and postproduction. Here are some examples:

1. The Lion King (2019): The filmmakers used Unity to create a virtual reality version of the African savannah, which they used to previsualize the film's key sequences before filming began.
2. The Jungle Book (2016): Unity was used to create a virtual set for the film, allowing the filmmakers to shoot in a controlled environment and then add the animals and other elements in postproduction.
3. Blade Runner 2049 (2017): Unity was used to create a real-time environment for the film's visual effects team to work in, allowing them to preview and iterate on the effects more quickly.
4. Rogue One: A Star Wars Story (2016): Unity was used to create a real-time preview of a space battle sequence, allowing the filmmakers to make adjustments and refine the sequence before filming began.
5. Captain Marvel (2019): Unity was used to create a virtual reality environment for the filmmakers to use in previsualizing key sequences and planning camera movements.

Licensing Model

Unity offers a variety of licensing options to suit the needs of different types of developers and

organizations. As of 2023, here are the main licensing options for Unity:

1. Unity Personal: This is a free license for individuals and small businesses earning less than $100,000 in annual revenue or funding. It provides access to all of the core features of Unity, but is subject to certain restrictions, such as a revenue cap and limited support.
2. Unity Plus: This is a subscription-based license aimed at small businesses and individual developers who are earning more than $100,000 in annual revenue or funding. It includes additional features and benefits, such as higher revenue caps, priority support, and a license to use Unity for development on mobile platforms.
3. Unity Pro: This is a more advanced license aimed at larger studios and developers who require access to more advanced features and tools, such as source code access, advanced profiling tools, and additional platform support. It is a subscription-based license that requires an annual commitment.
4. Unity Enterprise: This is a customized licensing option for larger organizations and enterprises that require custom features, support, and training. It includes all of the features of Unity Pro, as well as additional support and consultation services.

Unity also offers licensing options for specific use cases, such as educational institutions, nonprofit organizations, and government agencies.

Introduction

Unreal Engine is a 3D computer graphics game engine developed by Epic Games. It is used to

create high-quality video games, as well as virtual reality experiences, architecture visualizations, and other interactive content for various platforms such as desktop computers, consoles, and mobile devices (Plante 2012).

Unreal Engine provides a variety of features and tools for game developers, including a visual editor, scripting tools, physics simulation, audio management, and asset management. It supports programming languages such as C++, Blueprints, and Python, and can export to multiple platforms such as Windows, Mac, PlayStation, Xbox, Nintendo Switch, iOS, and Android.

Unreal Engine is known for its powerful graphics capabilities, advanced physics simulation, and AI systems. It allows game developers to create highly immersive and interactive experiences, and is often used for creating high-end, AAA games. It is also popular among indie game developers due to its ease of use and accessibility, and the fact that it is free to use until certain revenue thresholds are met. Overall, Unreal Engine is a top choice for game developers who want to create visually stunning and highly engaging games and interactive experiences.

Versions of Unreal Engine

As of 2023, Unreal Engine has released five versions since its debut in 1998:

1. Unreal Engine 1: Released in 1998, it was used to create first-person shooter games like Unreal and Unreal Tournament.
2. Unreal Engine 2: Released in 2002, it added support for more platforms and advanced lighting and animation features.
3. Unreal Engine 3: Released in 2006, it was a major upgrade with improved graphics, physics, and game development tools. It was used to create popular games such as Gears of War and Batman: Arkham Asylum.
4. Unreal Engine 4: Released in 2014, it was another major upgrade with new features such as a visual scripting language called Blueprint, advanced physics simulation, and improved graphics rendering capabilities. It has been used to create high-profile games such as Fortnite, Borderlands 3, and Final Fantasy VII Remake.
5. Unreal Engine 5: Released in 2021, it introduces a new system called Nanite for rendering high-quality, film-quality graphics in real time, as well as Lumen, a global illumination system that enhances lighting and shadows.

Blueprint in Unreal Engine

Blueprint is a visual scripting system in Unreal Engine that allows game developers and designers to create gameplay mechanics, game logic, and other functionality without needing to write code. It is a node-based system, which means that developers can create complex interactions by connecting different nodes together.

Blueprints use a drag-and-drop interface, making it easy to create and modify game logic. The nodes represent different actions, events, and variables, and can be connected together in a flowchart-like manner to create a sequence of actions. For example, a developer could create a Blueprint that controls the behavior of a character, including movement, animation, and interaction with objects in the game world.

Blueprints also support inheritance and component-based architecture, which allows developers to create reusable components and behaviors that can be easily shared and modified across different parts of the game.

One of the benefits of using Blueprint is that it can help nonprogrammers, such as designers and artists, to create gameplay mechanics and other functionality without needing to learn how to write code. However, it is also a powerful tool for experienced programmers who can use it to quickly prototype and iterate on game ideas.

Unreal Engine Marketplace

The Unreal Engine Marketplace is an online platform where developers can buy and sell game assets, tools, and plugins for use in Unreal Engine.

It was created by Epic Games to provide a centralized location for developers to find high-quality assets and content to use in their games and other interactive projects.

The Marketplace offers a wide variety of assets, including 3D models, textures, sound effects, music, blueprints, plugins, and other game development tools. These assets are created by both individual developers and larger companies, and can be purchased for a fee or, in some cases, downloaded for free.

Using assets from the Marketplace can help developers save time and money by providing them with premade resources that they can use to quickly create and enhance their games. For example, a developer might use assets from the Marketplace to create game levels, character models, or environmental effects.

In addition to offering assets for purchase, the Marketplace also allows developers to sell their own creations to other developers. This can be a way for developers to earn income from their work and build a portfolio of game assets and tools that they can showcase to potential employers or clients.

Overall, the Unreal Engine Marketplace is a valuable resource for developers looking to create high-quality games and interactive experiences using Unreal Engine.

Unreal Engine in Hollywood Filmmaking

Unreal Engine has been used in Hollywood movies and TV shows to create stunning visual effects and virtual environments more cost-effectively. Here are some examples:

1. The Mandalorian: The popular Star Wars TV show on Disney+ used Unreal Engine to create its stunning virtual backgrounds and environments. This allowed the show to film in a much smaller physical space while still achieving the epic scale and detail of the Star Wars universe.
2. The Lion King: The 2019 live-action remake of the Disney classic used Unreal Engine to create the film's virtual environments, which included the African savannah and Pride Rock. This allowed the filmmakers to create photorealistic environments and characters that closely matched the original animated movie.
3. The Jungle Book: The 2016 live-action adaptation of the classic Disney movie used Unreal Engine to create the film's virtual environments and characters, including the lush jungle and its inhabitants. This allowed the filmmakers to create a visually stunning and immersive movie experience.
4. Blade Runner 2049: The sci-fi sequel used Unreal Engine to create its futuristic cityscapes and environments. This allowed the filmmakers to create a detailed and immersive world that felt like a natural extension of the original Blade Runner movie.

Licensing Model

Unreal Engine has a unique licensing model that offers developers different options based on their needs and budget. Here are the main licensing options:

1. Royalty based: This is the default licensing option for Unreal Engine. Under this model, developers can use the engine for free, but must pay a 5% royalty on gross revenue for any commercial products they create using the engine. With Unreal Engine 5, however, Epic Games waives their royalties margin for games until developers have earned US$ one million in revenue (Machkovech 2020) and the fee is waived if developers publish on the Epic Games Store.
2. Custom licensing: Epic Games also offers custom licensing options for large game studios or companies that have specific needs or require more flexibility than the royalty-based model provides. This option allows developers to negotiate their own licensing terms and can include options such as flat fees, custom support, and other services.
3. Unreal Studio: Unreal Studio is a suite of tools and plugins designed for architectural

visualization, product design, and other non-game applications. It offers a different licensing model which is subscription based and provides access to a range of additional features and support options.

Definitions

Head-related impulse responses (HRIRs) or head-related transfer functions (HRTFs, in the frequency domain) describe spatial-temporal acoustic properties of a human body resulting from the interaction of user's head, ear, and torso with the sound-field in space. The synthesis of a binaural anechoic spatial sound can be obtained by the convolution of an anechoic sound signal with left- and right-ear HRTFs chosen among a discrete set of measurements, i.e., spatial locations. Binaural and monoarual localization cues contained in the HRTFs allow users to experience a 360° spatial audio experience, being fundamental component for the immersive and realistic auralization in virtual/augmented reality and games.

Introduction

Multisensory integration is all the more vital in spatial perception where auditory cues assist visual attention for seeking potential dangers around primates and mammals (Holmes and Spence 2005), apprehending location and movements of a potential prey and communicating between peers (Gridi-Papp and Narins 2008). Human hearing incorporates perception of loudness, pitch, timbre, and spatial attributes of sound.

In particular, the auditory system is capable of estimating the location of sound sources in terms of direction and distance, as well as the spatial impression from the surrounding acoustic space. The position and movement of the listener inside the environment plays a key role in the perception of the characteristics of the listening space be it real or virtual.

Binaural anechoic spatial sound can be obtained by convolving an anechoic sound signal with left and right HRTFs over a discrete grid of spatial measurement points for a given listener and interpolated in order to synthesize arbitrary spatial locations (Xie 2013) (see Fig. 1a for a general schematic view of auralization). The minimum-phase characteristic of HRTF allows its decomposition in a pure delay, τ, followed by a minimum-phase system, $H_{\min}$:

$$H(\theta,\phi,r,\omega) = H_{\min}(\theta,\phi,r,\omega) \exp[-j2\pi f\tau(\theta,\phi,r,\omega)]. \quad (1)$$

where θ and ϕ denote source direction of arrival (DOA) in spherical coordinates and r source distance from listener head. Auralization algorithms largely benefit from this decomposition in terms of stability and performances (Schissler et al. 2016). The pure delay/time-shift can be defined as the monaural time of arrival (TOA), allowing inter-aural time difference (ITD) extraction considering the difference between left and right ear TOA. With the inter-aural level/intensity difference (ILD/IID), they are the basis of duplex theory for binaural lateralization of sound (Strutt 1907). In particular, ILD can be formally described by the following equation:

$$\mathrm{ILD}(\theta,\phi,r,f) = 20\log_{10}\left|\frac{P_R(\theta,\phi,r,f)}{P_L(\theta,\phi,r,f)}\right|, \quad (2)$$

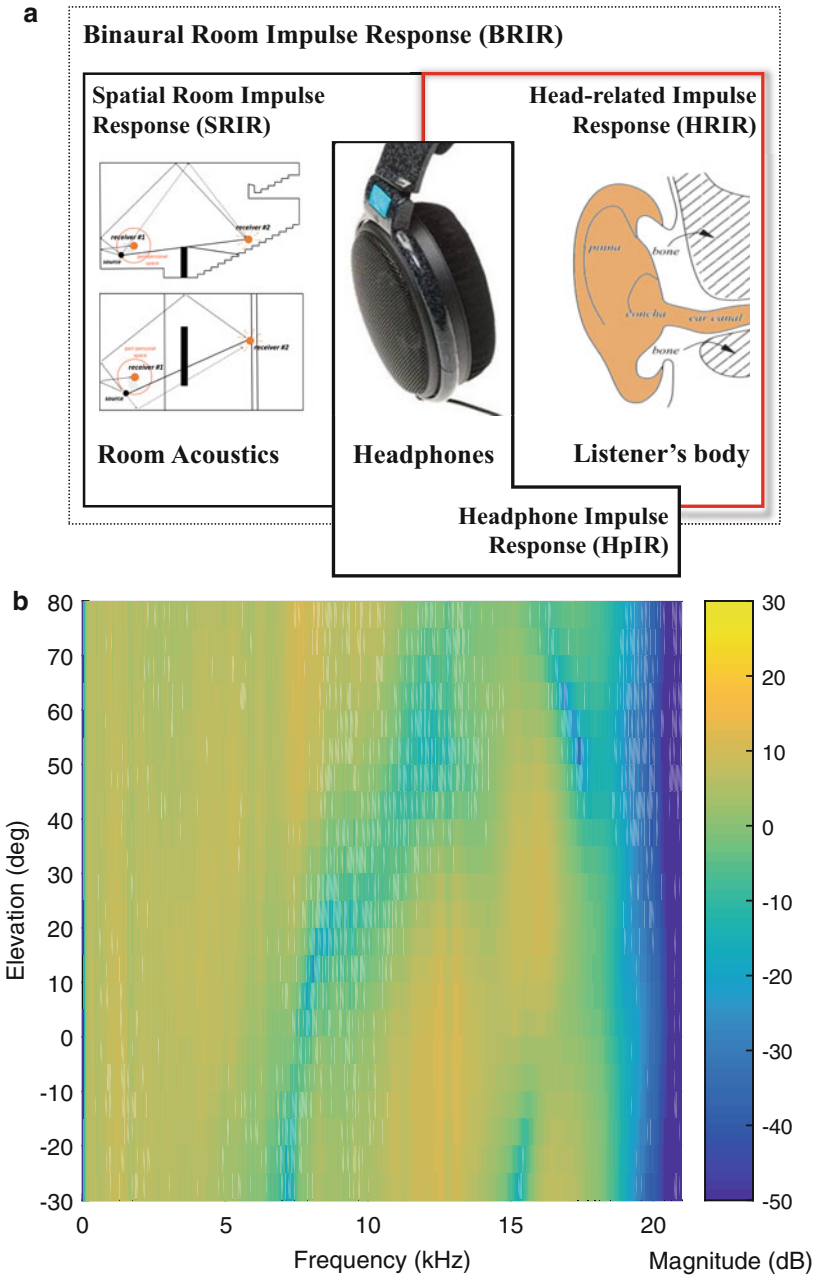
where $P_{L/R}$ indicates the sound pressure in the frequency domain generated by a sound source in a given spatial position at the left/right ear. ILD is relevant for high frequencies where the wavelength is smaller than the physical dimensions of the head, shadowing sound pressure at contralateral side. Dynamic localization cues due to head movements further strengthen ITD/ILD combination; accordingly, embedded IMU sensors in VR headsets become crucial for effective head-tracking and auralization.

Looking at the magnitude of $H_{\min}$ (see Fig. 1b for an example), Romigh and Simpson (2014) recently identified the intraconic spectral component as the main cause of inter-individual differences where pinna acoustics becomes dominant for localization in elevation. However, recording individual HRTFs of each user requires a trade-off between resources and time, because the measurement process is heavily prone to errors, and nowadays its complexity results unmanageable for any real-world application.

In multimodal virtual environments, a common approach is to use the same generic HRTFs, e.g., recorded using a dummy head such as Neumann KU-100 (see Fig. 2 for some visual examples), for any listener in order to obtain a trade-off between average efficacy and measurement/personalization procedures taking into account the dominance of visual cues for localization. However, generic HRTFs generally introduce unnatural coloration in the frequency spectrum and degradations in localization and immersion of the listening experience. Paul (2009) provided an historical review on this topic.

HRTF Personalization and Adaptation

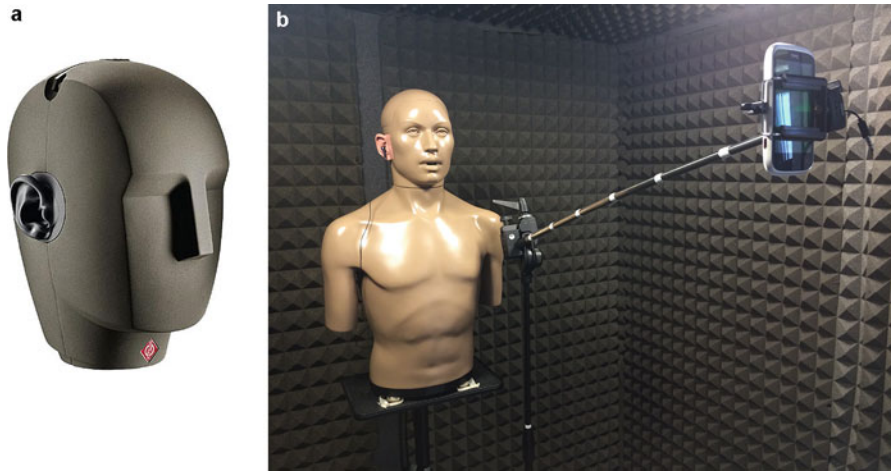
Dummy-head HRTFs can be considered an average template for user acoustics, introducing high uncertainty in localization due to differences with user anthropometry and to individual abilities in encoding generic directional information. Manipulating such HRTF template in order to personalize user acoustic contribution gives rise to different strategies: from the frequency scale factor based on anthropometric differences (Middlebrooks 1999) to ITD individualization with scaling procedures (Lindau et al. 2010), to name but a few. Moreover, one can allow users to directly manipulate a HRTF template using a series of bandpass filters to boost or attenuate specific frequency bands (Tan and Gan 1998). The post-manipulation phase usually requires user's involvement with



User Acoustics with Head-Related Transfer Functions, Fig. 1 (**a**) High-level acoustic components for VR auralization with focus on user acoustics. (**b**) Example of head-related transfer function variability for elevation in the frontal mid-sagittal plane of a Neumann KU-100 dummy-head. (Data taken from international research project "Club Fritz" (Andreopoulou et al. 2015))

listening tests in order to further iterate the process until the desired level of efficacy is obtained.

Recent literature is increasingly investigating the development of personalized HRTFs for each individual user in virtual/augmented reality in order to support a listening experience which is perceptually equivalent to that with own individual HRTFs. HRTFs can be computed from basic



User Acoustics with Head-Related Transfer Functions, Fig. 2 (**a**) Neumann KU-100 dummy head. (**b**) Example of a measurement setup on a KEMAR dummy head for HRTF personalization in the "SelfEar project" Geronazzo et al. (2016)

geometry of the head, pinna, shoulders, and torso and/or accurate numerical simulations with boundary element (BEM) and finite-difference time-domain (FDTD) methods (Xie 2013; Prepelita et al. 2016). Moreover, a structural interpretation of the acoustic contribution of head, pinna, shoulders, and torso can guide filter modeling of time and spectral (e.g., peaks and notches) variations (Geronazzo et al. 2013). HRTF features can be also defined according to principal component analysis (PCA) and subsequently personalized with self-tuning actions of weights (Hwang et al. 2010).

On the other hand, optimized selection procedures of existing nonindividual HRTFs is an alternative approach to personalization in which HRTFs are chosen by selecting the best match among several HRTF sets in a database. These approaches can benefit from the exponential increase of available HRTF data during the last 10 years, which has also provided motivations for standardization processes such as the Spatially Oriented Format for Acoustics (SOFA) (Majdak et al. 2013) (see also the official website of the SOFA project http://sofaconventions.org/ for an exhaustive list of freely available HRTF databases).

A user can select existing HRTFs in the domains of acoustic information, anthropometric features, and listeners subjective ratings (e.g., the most selected nonindividual HRTFs for a large user population). These procedures can be both automatic or guided by short listening tests aimed to assess the perceptual impact of nonindividual HRTFs for a given user. A training phase usually allows adaptation to nonindividual HRTFs thanks to automatic feedback such as correct-answer information to localization errors or audio-visual feedback adjustments. It is worthwhile to notice that there exist users able to better localize with nonindividual rather than individual HRTFs after an adaptation procedure (Klein and Werner 2016).

Conclusions

The need of a proper characterization of user acoustics is a key element for a realistic rendering in virtual reality scenarios, and it is even more crucial in immersive augmented reality settings where real and virtual sound sources are mixed in a natural listening experience (Ranjan and Gan 2015). Ensuring real life localization performances in VR becomes more and more important with close relations to presence, task-relevance, and effectiveness of the experience. Accordingly, users can increase their localization skills through

adaptation procedures directly in VR games which act as a training tool for remapping localization cues with nonindividual HRTF (Parseihian and Katz 2012).

Definition

Autonomous vehicles refer to vehicles equipped with advanced technology that allows them to operate and navigate without human interference. These vehicles are designed to sense their environment using various sensors and make decisions based on the collected data. Autonomous vehicles utilize artificial intelligence and sophisticated algorithms to perceive their surroundings, interpret information, and control their movement accordingly.

Semi-autonomous vehicles, also known as partially autonomous vehicles or Level 2/3 autonomous vehicles (according to the SAE International classification), are vehicles that blend automated driving capabilities with human control. Unlike fully autonomous vehicles, semi-autonomous vehicles require the presence of a human driver who is responsible for monitoring the driving environment and being prepared to take over control if needed.

Trust in the concept of autonomous vehicles refers to the confidence, belief, and reliance that individuals or society as a whole have in these vehicles to perform their intended functions safely, reliably, and efficiently. It encompasses the level of faith people have in the capabilities and performance of autonomous vehicles, as well as their perception of the technology's overall reliability, security, and ethical considerations.

Introduction

Autonomous vehicles are intelligent systems that are able to adapt continuously to their surrounding environment and move by sensing it (Yu et al. 2019) and without being interfered by human input (Fridman 2018; Wang et al. 2021). They are designed in six different levels of operation, including (1) No Automated driving, (2) Driver Assistance, (3) Partial Automation, (4) Conditional Automation, (5) High Automation, and (6) Fully Automated Driving (SAE 2014; Wang et al. 2021).

The focus of this entry is on fully automated cars. These vehicles usually work considering

User Interface (UI) in Semiautonomous Vehicles, Table 1 How autonomous vehicles work (Barber 2022)

Perception	Prediction	Planning
What is this object? Where is it?	Where will it go?	How do I navigate?

three main concepts: (1) perception, which means finding out what are these objects around the vehicle at different angles and where are their exact location, (2) predicting where they will go; and (3) planning how the vehicle navigates to reach the destination (Barber 2022) (Table 1).

One of Artificial Intelligence's (AI) most significant challenges is making technologies interactable, without struggle and challenges, and making design transparent and immersive (Steven 2017). For example, although using a self-driving car seems fun, interacting with these vehicles is not always easy. The imagination of future autonomous cars with perfect User Interface (UI) might seem impossible; one might enter the car, order it where to go, chill, watch a movie, or take a nap. In individuals' imagination, it sounds fancy. However, the problem is complex and needs to be examined using passengers' experiences in different aspects to design and implement a more user-friendly self-driving car (Steven 2017).

This entry covers state-of-the-art technologies and discusses the current thoughts on user interface and user experience design in autonomous cars. This entry aims to propose the important concepts and issues of developing a fully automated vehicle in terms of UI design.

UI in Semiautonomous Vehicles

Considering the interactions in autonomous vehicles, state-of-the-art Human-Computer Interaction (HCI) technologies refer to the design of control transitions from the driver to the automated vehicle. Moreover, automated vehicles need to support tasks unrelated to driving once the drivers are assumed to be passengers in the car (Pfleging et al. 2021). The first important issue in this process is whether the passenger can trust the automated vehicle or not. To improve the trustworthiness of autonomous vehicles, it is important to increase the interaction between passengers and the vehicle through user interfaces.

Trust

Through the transition toward automated vehicles, new challenges are expected as the responsibilities are shifted from the driver to the vehicle. Implementing shared control between them also raises some challenges in semiautomated vehicles. Some of these challenges are creating and maintaining situational awareness and finding solutions to build trust while maintaining user acceptance of automation technology (Pfleging et al. 2021). As a passenger in a manual car, you can easily interact with the driver and ask them where they are going, or in case you are the driver, you know that you are in control of everything. Also, people and other drivers will know that the car has a driver who is careful about them and knows the rules. So, in a word, there is trust, and when the vehicle does not have a driver, it is harder to trust it. Consider a bicyclist riding on the road; when they see a car that wants to turn, they will make eye contact with the driver and ensure that the person notices them. Even the drivers may show them with their hands that they are waiting for them to pass. All these clues assure people in the street that they are safe around this car. Considering these examples, to build trust in automated vehicles, there is a need to predict the next action and a need to communicate (Steven 2017).

Communication Design

Once the control and responsibilities are shifted to the automated vehicle, a new challenge is to develop systems to communicate with pedestrians, cyclists, or drivers of manually driven vehicles (Pfleging et al. 2021). The passengers in autonomous cars are probably involved with non-driving-related tasks, and therefore, they do not monitor the road. In such a situation, other road users may not be able to communicate with the driver, and technical solutions are crucial to

replace the traditional form of communication with a new one. The influence of such communication concepts on driving behavior, traffic flow, and social acceptability can play an essential role in future traffic situations. To address this issue, there is a need to see what the machine sees and gets as input. However, just visualizing all the data that sensors gather could be confusing and is not enough. For example, there is a need for a user-friendly Human Machine Interface (HMI) to be developed so that a user with no experience in object detection or working with sensors can understand. So the user interfaces should be simple, straightforward, and correct.

While it should have this intractable simulated surrounding, it also should be informative enough for both driver and passengers. Similar to all the regular navigation applications, information about the traffic, the remaining distance, and the time to reach the destination should be provided for passengers. Moreover, specific information about the car's working status, like speed and battery situation, is also crucial.

Interior Design

While passengers are not busy driving in the car, there might be a need to provide entertainment for passengers in the vehicle (Sener and Bahar. 2020). To explain more, the interior should convert into an office, living room, or dining room, or may even support relaxation and sleeping (at least in the far future) to allow the passengers to take advantage of the free time they have during their trip. This automatically leads to reconsidering some factors ranging from redesigning the car's interior based on their needs to employing modern materials to create and facilitate the ride for both passengers and drivers (Pfleging et al. 2021).

This is the point that the role of infotainment becomes even more important, which we will discuss in the following chapter.

Literature Review

Research about different aspects of autonomous vehicles is still attracting academic attention. In the case of user experience design for autonomous cars, different research was conducted to determine how passengers' experiences can lead us to design and implement a more user-friendly self-driving car. In Sen and Umulu's work, a workshop was held to ask participants in an experiment to examine different scenarios to define activities that an infotainment system could make in separate modes, which is trying to enhance UI features and functionality in semi-autonomous cars. Various modes are described in the (Sen and Umulu 2021) paper, whether the passenger chooses to interact with the infotainment system, pay more attention to the surroundings, or consider both. Therefore, the UI system will work on the passenger's priority. When passengers are completely informed about the trip and what the car is doing, our motivation for improving this kind of infotainment system in autonomous vehicles is to let the passengers have a connection to social media, interact with other cars, and not feel excluded from the journey (Ohad and Noam 2011; Sener and Bahar 2020). These issues are not only happening in autonomous cars but also in regular cars. For example, in Berger and Collab's work, an interactive car window and door panel are introduced to help the passenger in the rear seat to interact more with the surroundings (Berger et al. 2021).

Conclusion and Discussion

In conclusion, the main points that should be considered in UI in autonomous vehicles are as follows:

First, self-driving cars are not a dream anymore, and now the new challenge is improving UI and UX design for these vehicles. Second, better UI design will result in more trust in self-driving cars, which is crucial for autonomous vehicles. And finally, UI/UX design for autonomous vehicles is not just limited to the technical representation of the trip but also includes all the personal aspects related to the driver, like making the person informed, entertained, and involved.

User-driven development framework for virtual reality setups: a development methodology for virtual reality systems, that puts the user central

in a cyclical development process, iteratively clarifying the usability goals for the setup in terms of the user, system, and organizational characteristics and needs, and systematically matching these onto the technologies, interfaces, and processes to be developed, in order to achieve a time- and cost-effective development process, and a VR Setup with a satisfactory user experience, with efficient task and workflow, giving extensive attention at each stage of the design process to evaluating the user experience and user interface.

User-Centered Software Development for VR

The user-centered software development methodology framework consists of systematic information elicitation and documentation, in incrementally more detailed stages and using progressively more complex information elicitation activities, as summarized in the text and diagram below. User-centered software development progresses in an iterative process of clarification and refinement of the application requirement descriptions, based on input and feedback from all stakeholders, product owners, and representative end-users. User- and system-requirements information is continuously collected from them and then analyzed and documented by the development team. The team ideally consists of one or more user interaction designers, user interface developers, software developers, and preferably at least one representative end-user (Eastgate et al. 2014; Tromp et al. 2003). All requirements analysis information is documented in the requirements specification, in order to create a common and clear reference document for the development tasks and help manage and coordinate collaboration within the team. Development can start as soon as a first pass has been made through the framework and the minimum viable product (MVP) specification has been described. Not all details for the application can be known in the first or second pass through the framework. Often details only become apparent after several passes through the framework, which is why this methodology is an iterative development process. Similarly, in the early phases of the development process, the user-centered tests will take place on simple or partial prototypes. With each pass through the framework, testing methods will be more complex, in order to assess the progressively more detailed prototypes. This user-centered development methodology framework helps to focus from the start of the development process, on the needs and expectation of the end-users of the application, and it helps to structure the way in which the development team collaborates. The diagram of the framework for this development methodology (see Fig. 1) shows the stages of the development process and the procedural feedback loops, going back to all previous stages, signifying the continuous iterative refinement of the information needed for the development of the user experience, user interface, and system functions.

Definition

UV map is a bijective mapping from a surface to a 2D domain. Each vertex on the surface has XYZ coordinates representing the position of a space. The corresponding vertex in 2D domain has UV coordinates ranging from 0 to 1.

Triangular mesh is a collection of vertices, edges, and faces that describes a 3D shape in computer graphics. Most of parameterization methods give a restriction that the input mesh should be a 2-manifold.

Introduction

UV Map generation is an essential process in 3D modeling. Given two surfaces with the same topology, the bijective mapping between them is called mesh parameterization so that UV map is a special case of mesh parameterization. Many applications such as texture mapping, morphing, mesh completion, model compression, remeshing, etc., need a good UV map as a prerequisite. A good UV map is characterized by following properties:

Low stretch. UV map usually has a degree of distortion in order to keep the topology. A low-stretch parameterization is approximately isometric that avoids changing area and angles of each triangular face. To obtain high resolution texture mapping or other benefits in particular applications, low-stretch UV map provides a solid foundation.

Low charts number. Atlas-based UV map, composed of several nonoverlapping free boundary charts, is used for various 3D modeling techniques (e.g., normal map, remeshing, morphing, etc.). A small amount of charts, however, cause more stretch while combining two small charts into a big one provide the integrity of a chart which representing one semantic part of the 3D model after parameterization.

Reasonable cuts. Triangular mesh, achieved by artificial design or computer synthesis, is a generally complete and continuous surface that

needs to be cut into minor parts before parameterization. The seam between two charts should be as invisible as possible so that it is supposed to cut on sharp angle boundary and in low visibility region, rather than in high detailed area.

A large number of research on surface parameterization have been published. Hormann et al. (2008) gives a survey in early year. Angle preserving method including ABF++ (Sheffer et al. 2005), stretch-driven method like iso-charts (Zhou et al. 2004), almost isometric method (Pietroni et al. 2010), quantized global method (Campen et al. 2015), etc., perform well in practical application. A novel UV Map generating method proposed recently allow parameterization can be represented in different levels-of-detail (Tarini 2016). This chapter will introduce a traditional method that generates a UV map under a user-assigned distortion threshold.

Stretch-Driven Mesh Parameterization

To generate an ideal UV map, a constrained stretch value is assigned by user. Two norms of stretch were proposed in Sander et al. (2001). The L_2 norm integrates over the surface where there are largest and smallest singular values of the Jacobian corresponding to the affine matrix which representing the mapping from texture space to model space at any point. The $L\infty$ norm maximizes $\{\gamma_{max}, 1/\gamma_{min}\}$ over the surface. Spectral Analysis proposed by Zhou et al. (2004) was one of the most popular stretch-driven mesh parameterization algorithms. It is composed of following parts:

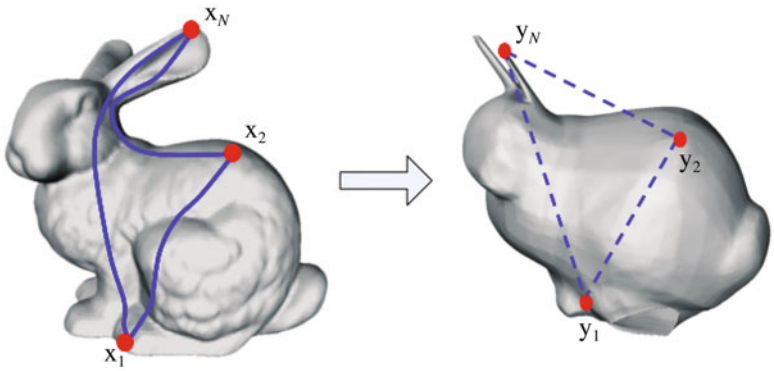
1. Compute the surface analysis as the initial parameterization
2. Perform iterations of stretch optimization (Sander et al. 2001.
3. Split surface into charts using spectral clustering
4. Optimize chart boundaries using signal-based graph cut
5. wPlace charts into a 2D space with UV coordinates to generate an atlas-based UV map

Spectral Analysis

Given a set of points on a high-dimensional manifold, Isomap (Tenenbaum et al. 2000) computes geodesic distances along the surface. Then it finds an embedding in a low-dimensional space whose Euclidean distances are similar to the corresponding geodesic distance in high-dimensional space. Figure 1 shows an example of spectral analysis.

Spectral analysis is built upon Isomap, containing following steps:

1. Given a surface with N vertices, $\mathbf{x}_i$, compute squared geodesic distance between each pair of



UV Map Generation on Triangular Mesh,
Fig. 1 Spectral analysis for the Stanford bunny. Left one is origin model. Right one is the model after spectral analysis in three-dimensional embedding space. The geodesic distance in left one is similar to the Euclidean distance in right one

vertices along the surface. A symmetric matrix $\mathbf{D}_N$ represents these geodesic distance data.
2. Normalizing $\mathbf{D}_N$ using identity matrix $\mathbf{I}$ and centering matrix $\mathbf{J}_N$

$$\mathbf{B}_N = -\frac{1}{2}\mathbf{J}_N\mathbf{D}_N\mathbf{J}_N,$$

where $\mathbf{J}_N = \mathbf{I} - \frac{1}{N}\mathbf{1}\mathbf{1}^{\mathrm{T}}.\mathbf{1}$ is a vector of ones of length N.

3. Compute eigenvalues λ_i and their corresponding eigenvectors $\mathbf{v}_i$.
4. For each vertex $\mathbf{x}_i$, embed it in a new N-dimensional space. The new vector $\mathbf{y}_i$ is

$$\mathbf{y}_i^j = \sqrt{\lambda_j}\mathbf{v}_j^i.$$

Not all of N vertices are needed to represent the energy of the surface. Actually top five eigenvalues constitute over 85% of the squared energy. Therefore, *n-dime*nsional embedding space is recommended for spectral analysis. n is calculated by dominant energy (Zhou et al. 2004).

The distortion of each embedded vertex i called geodesic distance distortion(GDD) can be defined as:

$$GDD(i) = \sqrt{\frac{1}{N-1}\left(\sum_{j=1}^{N}\left\|\mathbf{y}_i - \mathbf{y}_j\right\| - d_{geo}(i,j)\right)^2},$$

where $d_{geo}(i, j)$ is the geodesic distance between i and j. The key idea of parameterization using spectral analysis is setting $n = 2$ to minimize the sum of squared GDD over all vertices (Zigelman et al. 2002).

Stretch Optimization

To minimized $L2$ and $L\infty$ after initial parameterization, Sander et al. (2001) exploit a uniform-edge-spring solution and then perform several optimization iterations.

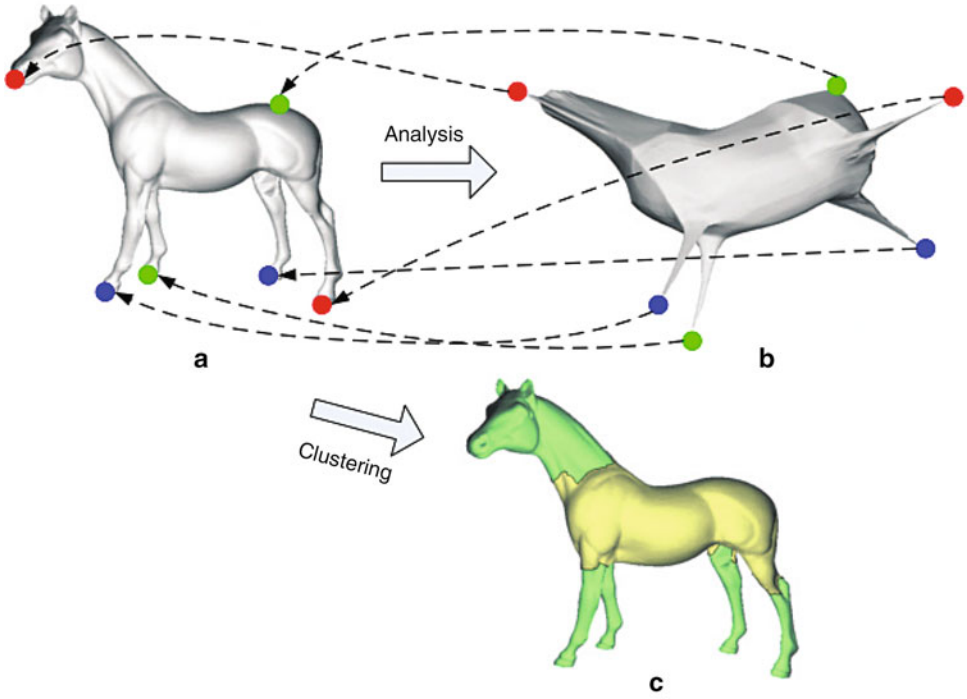
For each iteration, choose the vertices by decreasing order of neighborhood stretch. Then perform a line search minimization along a random direction in texture space. The line search is constrained within the kernel of neighbor because the metric is infinite for degenerate or flip triangles. While succeeding the iteration, the convergence tolerance is decreased using $1/k$ where k is the iteration number.

The post-optimization initial parameterization decreased stretch, even if it is still over user's assignment. Spectral analysis method will always split charts whose stretch is above user's assignment and guarantees the final result will not contain flip triangles. Instead of general optimization, Zhou et al. (2004) proposed a landmark method in both chartification and parameterization.

Spectral Clustering

The triangular meshes are not always disk-like. We need to partition the surface into a certain number of charts. As a simple truth, the stretch of parameterization declines with the increase of charts number. Recall that global features of a model such as heads, limbs, and tails are related to larger eigenvalues. Zhou et al. (2004) use spectral analysis to find *landmarks* of a model and exploit them to generate charts. This method called *surface spectral clustering is* composed of following steps:

1. Sort the eigenvalues λ_i computed during initial spectral analysis by decreasing order ($\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_N$).
2. Find n which maximizes λ_n/λ_{n+1}
3. For each vertex i, compute its n-dimensional embedding coordinates: $\mathbf{y}_i^j = \sqrt{\lambda_j}\mathbf{v}_j^i (j = 1, 2, \ldots, n)$, where $\mathbf{v}_j$ is the corresponding eigenvector of λ_j
4. Find maximum and minimum coordinate value vertices in each dimension to get totally $2n$ representatives. Remove some of them which are too close to each other, yielding $m \leq 2n$ *landmarks* whose embedding are these representatives.
5. Cluster triangles on the mesh into closest growing charts around m landmarks.



UV Map Generation on Triangular Mesh, Fig. 2 Spectral clustering for a horse model. The vertices with same color are in the same dimension (Zhou et al. 2004)

Use the geodesic distance calculated in previous spectral analysis.

Figure 2 visualizes the spectral clustering method on a horse model. When set $n = 3$, the sum of top three eigenvalues occupy 85% of total energy (energy is proportional to eigenvalue). Therefore, embedded model has homogeneous shape to the origin one and landmarks are located on high frequency surface which means the place has more details.

Boundaries Optimization

The chartification using spectral clustering, however, provides a reasonable partition, brings the issue that boundaries of charts are not smooth, and frequently splits a complete surface into several parts. The ideal chartification has almost invisible chart boundaries that cuts should be distributed on divide between two surfaces with big dihedral angle or the surface with low visibility such as back face of a sofa.

To achieve the reasonable cuts, (Zhou et al. 2004) formulate the optimal boundary problem as a graph cutting problem. Suppose the boundary of two adjacent charts **A** and **B** need to be optimized, the optimization includes following steps:

1. Generate a medial region **C** by expanding a region from the initial split boundary.
2. An undirected flow network graph can be constructed from **C** using an extension of the method in Katz and Tal (2003).
3. Define the capacity $c(f_i, f_j)$ between two adjacent triangles f_i and f_j

$$c\left(f_i,f_j\right) = \alpha c_{ang}\left(f_i,f_j\right) + (1-\alpha)\mathrm{c}_{sig}\left(f_i,f_j\right).$$

The first term corresponds to the objective that cut through edges of high dihedral angle. Katz and Tal (2003) give the formula that $c_{ang}\left(f_i,f_j\right) = \left(1+\frac{d_{ang}\left(f_i,f_j\right)}{avg\left(d_{ang}\right)}\right)-1$,

where angular distance is defined by $1-\cos\alpha_{ij}$.

The second term corresponds to the objective that cut through edges of user's specification. Signals are used to achieve a property of surface, including color, normal vectors, illumination, and visibility. *Integrated metric tensor* (IMT) (Sander et al. 2002) encapsulates how much the signal varies over the surface. Therefore *signal distance* from vertex i to vertex j is given by

$$\sum_k (p_k - q_k)^T M_k (p_k - q_k),$$

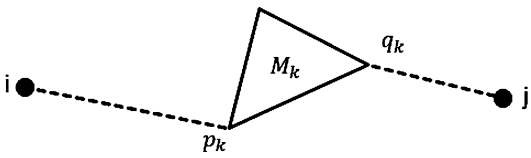
where k is the triangle along the path from i to j and M_k is IMT of the triangle k. p_k and q_k are the signals at end of the path though triangle k, see Fig. 3.

GDD with signal distances, then calculate $c_{sig}(f_i, f_j)$

$$c_{sig}\left(f_i,f_j\right) = \frac{d_{sig}\left(f_i,f_j\right)}{avg\left(d_{sig}\right)}$$

$$d_{sig}\left(f_i,f_j\right) = \left|GDDA(f_i) - GDD_B(f_i)\right| + \left|GDDA(f_i) - GDD_B\left(f_j\right)\right|$$

4. Use graph cut algorithm to achieve new boundary. Zhou et al. (2004) give some boost method to reduce the time consumption.



UV Map Generation on Triangular Mesh, Fig. 3 Signal distance

UV Maps Packing

Atlas-based UV map is the most simple way for users' recreation. Packing parameterized charts into texture space need to fully utilize the area. In Lévy et al. (2002), a Tetris algorithm was introduced. A more simple method is that given the user specified width and height, rescale each chart to make its area in the texture space equal to its area in 3D domain. Then sort them by decreasing area order. For each chart, rotate and put it into UV domain in order to minimize the waste space.

Open Source Tools

The parameterization algorithm has difficulties on implementation. Many commercial software like Autodesk Maya have built-in tools to generate the UV map. Fortunately, there are some open source projects on Internet so that we can get taste of the algorithm.

UVAtlas (Huang and Walbourn 2014) is a shared library for creating and packing an isochart texture atlas held on Github. It implements the spectral analysis algorithm and an end-to-end UV map generator. Figure 4 shows several results generated by UVAtlas.

Other parameterization algorithms such as ABF++ also have open source projects. Graphite (Lévy 2008) is an experimental 3D modeler, built on top of the Geogram programming library. It has data structures and efficient OpenGL visualization for point sets, meshes (triangles and polygons), volumetric meshes (tetrahedra and hybrid meshes).

Conclusion

UV map generation on triangular mesh is a heavy studied topic in computer graphics. Using open source code like UVAtlas could generate good result with user's specification. This chapter gives a general outline of traditional stretch-driven method, which is an effective pipeline to finish the UV map generation task.

Definition

Computer graphics comprised of mathematically derived lines, polygons, and curves.

Description

The term "vector graphics" refers to a method of generating electronic images using mathematical formulae to calculate the start, end, and path of a line. Images of varying complexity can be produced by combining lines into curved and polygonal shapes, resulting in infinitely scalable objects with no loss of definition (Fig. 1).

Vector graphics can be generated via a variety of computational and display technologies, including analog machines using cathode ray tubes. William Higinbotham, for example, famously displayed his 1958 game *Tennis for Two* (Higinbotham 1958) on a repurposed oscilloscope (Fig. 2).

Vector graphics are elemental to computer game history, especially the computer game history of the 1970s and 1980s when the medium was first commercialized. Though arguably less versatile than raster graphics, the wireframes of early vector games such as *Space Wars* (Cinematronics 1977), *Battlezone* (Atari 1980), and *Tac/Scan* (Sega 1982) could be rendered more quickly by their era's hardware, producing more fluidly animated and interactive elements on screen. As a result, it became possible for game

developers to create simple but functional three-dimensional environments, opening the game medium to new designs and immersive possibilities.

Public interest in vector graphics predates the advent of the computer game, however. As early as the mid-1940s, photographs of artfully arranged oscilloscope plots were common in *Popular Science* and other large circulation magazines. In the late 1940s, pioneering electronic artists such as Ben Laposky began to popularize "oscillographic art," and by 1951, scientists and engineers were receiving considerable public attention for their use of cutting-

edge computers such as MIT's Whirlwind, which featured a vectorscope-type graphics display designed to plot the X-Y relationship between two signals rather than the more common display mapping the change of one signal over time.

By the mid-1950s, a vector-based light pen had been created to allow direct user interactions with vector graphics, and in the late 1950s, William Fetter, a commercial artist working for Boeing (and coiner of the term "computer graphics"), began experimenting with vector graphics to better understand the integration of the human body and an aircraft cockpit. Striking for their beautiful representations of the human form – sitting, leaning, and stretching – these figures, which were drawn using an IBM 7094 punch-card system and a Gerber plotter, came to be known as "Boeing Man," and are now considered to be among the first examples of popular computer art. Other companies soon began to experiment with vector graphics in their own ways, including Information International Inc., McDonnell Douglas, General Electric, General Motors, and Bell Labs.

Vector graphics had become sufficiently common by the mid-1960s that Hank Stockert, Norman McLaren, Edward E. Zajak, Mary Ellen Bute, Hy Hirsh, and other artists were able to build careers on manipulated oscilloscope vector signals. Their numerous art exhibits, public lectures, and commercial art portfolios reflected the growing popularity of this emerging visual style. In 1967, only a few years after Ivan Sutherland created *Sketchpad* (Sutherland 1963) – a vector-based drawing program and progenitor of today's CAD/CAM systems – and Doug Englebart built the first computer mouse, digital arts pioneer Charles Csuri created *Hummingbird* (Csuri 1967), a 10-min animation using vector-interpolated 16 mm film. The techniques deployed in this and related cinematic and photographic projects became the foundation for Cranston/Csuri Productions (CCP), one of the world's first computer animation companies (Sito 2013). Yet more than a decade before companies such as CCP began to heavily commercialize vector graphics, Evans & Sutherland – the first computer graphics company – developed a vector-based system equivalent to technology previously only available at high-end military research and development facilities. Two years later – 1970 – William "Boeing Man" Fetter was part of a team that produced an ad for Norelco razors, the first vector-based computer-generated television commercial.

Though the rise of affordable raster technology in the late 1970s blunted research and fine art interest in vectors, the aesthetic remained relatively popular through the 1980s, thanks to coin-operated computer games such as *Asteroids* (Atari 1979) and *Tempest* (Atari 1981), films such as *Return of the Jedi* (20th Century Fox 1983), and music videos such as Mick Jagger's "Hard Woman" (Columbia, 1985). In fact, vectors were even faked in a number of feature-length films (e.g., *Escape from New York* [Avco Embassy Pictures 1981], *Outland* [Warner Bros. 1981], *Inseminoid* [Butcher's Film Service 1981]). Clearly entranced by the vector aesthetic but working with budgets inhospitable to the massive special effects spending necessary to create elaborate computer-generated imagery, filmmakers and other media makers concocted all manner of analog techniques to produce the look of advanced computer graphics without their attendant expense.

Public interest in vector-based graphics during the late 1970s through the 1980s may also be attributed to corporate concentration and conglomeration. Warner Communications' 1976 acquisition of Atari, for example, enmeshed game software and hardware into the sphere of vertically and horizontally integrated transnational media, a convergence that helped translate the specific technical advances of vectors into mass mediated commodities. Warner's production and marketing of vector-infused television, film, and games helped to familiarize and cement the public's appreciation of vector aesthetics and their futuristic significations.

Apart from subsequent periodic fits of cultural nostalgia, the development, use, exploitation, and

imitation of vector graphics in computer games and other media subsided by the late 1980s. Computer hardware, firmware, and software had developed to the point of being able to readily produce sophisticated, smoothly animated, and visually flexible raster graphics. Despite this change, however, vector graphics continue play an important role in computer game development. Many studios, for example, depend heavily on vector graphics to produce visual content for their projects, especially if those projects involve three-dimensional objects. As has always been the case, the generation of numerous concurrent and/or complex vector models tends to be highly resource intensive, and thus game developers now typically rasterize a project's vector graphics once the game build is finalized in order to reduce its computational resource footprint. This relatively simple workflow from vector to raster graphics gives modern day developers the best of both worlds: a highly dynamic development environment that ultimately yields an evocative – and highly efficient – consumer deliverable.

Definition

"Video game culture"	New media subculture that has emerged around the global popularity of video games. Scholarly researchers have looked

	at video games from a cultural studies perspective in relation to identity, practice, thinking, learning, gender, children, conflict, and history (Shaw 2010, 1).
"Regional game studies"	Studies which investigate games and gaming cultures "at a range of geocultural scales, identifies connections across and between these scales, highlights and addresses unequal global power relations within gaming culture and within the academic study of games, and enriches the field with new perspectives drawn from regional cultural contexts" (Liboriussen and Martin 2016).
"Paranodal Play"	play practices that are "un-networked, offline and untrackable" (Pallitt et al. 2019.
"Global South"	An situational term coined by Walter Mignolo in his essay "The Global South and the World Dis/Order" (Mignolo 2011) to describe countries which were on the receiving end of globalization and colonialism, and still endure the effects of colonialism to this day.

Introduction

"Game culture" is most frequently defined through descriptions of gamers and their collective practices and identities (Shaw 2010). As elsewhere in the world, gaming is a ubiquitous practice in Cape Town, South Africa. Young people play games on consoles, PC's, and mobile devices. They do so at home, on the move, in arcades, cybercafes, and libraries (Pallitt et al. 2019). Yet income inequalities greatly influence consumption patterns and, in turn, shape gamers' experiences of digital games (Walton and Pallitt 2012).

Early South African research into gaming reported computer game development projects (Amory et al. 1999), scripting environments (Elliot et al. 2009), and the use of games in, for example, mobile maths tutoring (Butgereit 2007). A small body of studies from Cape Town are beginning to address the significance of gaming in children and young South Africans' everyday lives (Pallitt et al. 2019).

Studies of video game culture in contexts of the global South have shown that there are great regional differences in gamers' experiences of games and their subsequent gaming cultures, related to content, context, and infrastructure (Penix-Tadse 2019). In Cape Town, differential access to infrastructure for gaming can be observed at three different scales: participation in mainstream global gaming culture, participation in "indie" gaming culture, and the cultures of "paranodal" (Mejias 2013) games communities who are less easily documented.

Mainstream Video Game Culture

Vizeum's Consumer Connection Survey estimates that around 11.4 million people play games on consoles in South Africa, while 5.8 million play mobile games (Hall et al. 2017). *Grand Theft Auto V* and *Fifa 20* are the best-selling titles for PlayStation and Xbox consoles in 2019 (Prior 2019), while *Dream League Soccer 2020* and *Real Commando Secret Mission* (*Free shooting games*) topped the lists for mobile devices (SimilarWeb 2020).

Cape Town hosts a number of expos and fan conventions to cater to this vast community of gamers. *Afresports*, *Ucon*, *ComicEx*, *FanCon*, *EGE,* and the *Canal Walk gaming expo* are all based in Cape Town and cater to "gamer and geek culture" (Dredd 2019) in the city. These mainstream events focus on AAA games titles, e-sports, and Local Area Network (LAN) competitions.

Skotnes-Brown has argued that the legacies of colonialism have greatly influenced video game culture. For example, she has shown how the local chapters of the *Dota 2* community, the multiplayer online battle arena game (MOBA), are riddled with toxic and racist behaviors (Skotnes-Brown 2019). Skotnes-Brown has argued that this reflect a broader structural problem associated with "hardcore" gaming – largely considered a white

male hobby – where racist attitudes emerge in "safe spaces" provided by online anonymity.

Nevertheless, in 2016, the measurable mainstream popularity of video games drew the attention of government bodies such as the department of Economic Development and Tourism (DEDAT) and industry associations such as Cape Innovation and Technology Initiative (CiTi), Interactive Entertainment South Africa (IESA), and the Cape Craft and Design Institute (CCDI) to motivate for the potential of Serious Games to "address prevalent social challenges throughout South Africa, and particularly the Western Cape" (Hall et al. 2017, 1). In a "State of Gaming Report" from 2017, Hall et al. argue that serious games can be applied locally to tackle social problems, advance research in science and technology, advance innovation, supplement education, and advance medical therapies Hall et al. 2017, 6–7). In order to harness this power, these organizations launched the "Serious About Games" initiative, which invited local indie developers to pitch serious games concepts in collaboration with local NGO's (Serious About Games 2016).

Indie Video Game Culture

"Indie gaming," and particularly concepts of "indie game culture" (Simon 2013), changes our scale of focus to the production, in addition to the playing, of games. Simon argues that the term "indie" forces scholars of games to shift our analytic attention to the provenance of the game – those who made it and the conditions under which the games were made and distributed: "to speak of indie games is not to speak only of the games themselves or of the experiences of gameplay but rather of the cultures of game development from whence they came" (Simon 2013, 2).

In South Africa, a central pillar of video game culture is embodied by Cape Town-based independent organization "Make Games South Africa" (MGSA) – an association that supports and connects local game developers through forums and monthly meet-ups. MGSA can be seen as a "cultural intermediary" in promoting and supporting indie game development (Parker et al. 2018), connecting developers with collaborators, funding and distribution opportunities (Hall et al. 2017). As of 2017, there are 15 full-time games studios in the city of Cape Town (Hall et al. 2017, 9). With many more freelance or hobbyist game developers creating games in the city, games such as *BroForce (Free Lives), Desktop Dungeons (QCF design),* and *Genital Jousting (Free Lives)* have been developed in Cape Town, winning numerous awards and accolades.

Beyond the online forums and monthly meet-ups, indie game developers in Cape Town meet up at "game jams" – events where game developers as well as novices can collaborate on creating new games or game prototypes in a time-constrained environment (typically 48 h) (Preston et al. 2012). Members of MGSA host physical locations for major annual international game jams such as the *Global Game Jam* and *Ludum Dare*. In terms of local initiatives, the *South African Game Jam* is hosted by *Free Lives* (a studio based in Cape Town).

In term of exhibitions, indie game developers are able to display their work at the *Super Friendship Arcade* (*https://www.facebook.com/superfriendshiparcade/*) – a sporadic pop-up exhibition of games and hardware made by the community, and at a more professional level, at the annual *Playtopia* Festival (*https://www.playtopia.co.za/*), which is held every December since 2018 at the Castle of Good Hope. These events also host their own jams to create content for their playful media exhibitions.

Paranodal Video Game Culture

Beyond the scale of main stream and indie culture, many gamers in the city of Cape Town experience games in a way that is "paranodal" (Mejias 2013) – at the margins or completely outside of digital networks. Many of these gaming practices emerge as part of a broader phenomenon of "pavement internet" (Walton 2014) where information (including digital goods such as images as games) downloaded from the web trickle down through interpersonal networks at low data costs. For many of the city's poorest residents, games are only an option if they are either free or very low cost. That does not mean that these cultures are

not thriving. Frequently these practices go unregistered on the network. For example, gaming that happens in public access venues such a libraries and cybercafe's, on mobile devices where games have been cloned by Wifi-Direct sharing applications such as *ShareIt,* and on older modified consoles with pirated games (Pallitt et al. 2019).

In Cape Town libraries, as in many similar sites globally, public access computers were first appropriated by young people, particularly young men and boys. These groups were attracted to the venues at least in part because of their interest in games (Valentine 2004). Early evaluations of the provision of internet access (known as the "SmartCape" project) pointed to the ways groups of boys and young men monopolized the facilities, congregating around computers for long periods (Sooful et al. 2002). Valentine (2004) reports that libraries responded to these early adopters in two ways. On the one hand, they made use of the collective know-how of informal experts by encouraging "volunteers" who helped others use computers and sometimes informally and unofficially charged small fees for doing so. On the other hand, the City libraries imposed time-limits and other restrictions on computer use. Library members were allowed to use the computers for any activity of their choice, barring the use of pornography, but they were restricted to short periods of time (usually between 20 and 60 min, depending on the demand and available facilities). Physically the library spaces and software system were configured to support silent individual reading or research with computers rather than embodied social play or the use of mobiles (Walton and Donner 2012).

Acknowledging young people's abiding interest in gaming, the Central Library was redesigned and now provides a specialized basement area set aside for children's books, where young people enjoy exclusive access to dedicated computers. These machines are often used for playing Flash-based internet games (Pallitt et al. 2019).

Another specialized gaming facility in Cape Town exists in Harare library, which was built as part of a project of urban upgrading of the Harare informal settlement area in Khayelitsha (Pallitt et al. 2019), with the overall intent of preventing violence in the area (Pallitt et al. 2019). Here a separate room is provided for gaming on computers and a Nintendo Wii console.

While there are few studies that explore gaming in domestic spaces within Cape Town, a handful of studies have pointed at the appropriation of video games as childcare in low-income areas such as Ocean View (Venter 2012) among children between the ages of nine and seventeen. Here households were not connected to the internet, and thus console gaming could only happen offline. Mobile devices, too, were intentionally disconnected to save on data costs.

Instead, young people invented their own digital games. For example, images of celebrities or other interests were collected or traded via Bluetooth in "swapping games," where mobile photo albums become a digital incarnation of the playground sticker album. Children would negotiate the relative value of images among one another: certain images were deemed more "expensive" owing to the data costs incurred to obtain them. These exchanges were largely gendered – with boys typically exchanging images of cars and girls exchanging images of celebrities (Pallitt et al. 2019).

Conclusion

A review of known video game cultures in Cape Town, South Africa, show diverse identities and practices tied to participation in gaming communities. This entry has highlighted three scales from which to observe culture within this context: mainstream, indie, and paranodal. These divergent cultures are influenced by video game content, context, and available infrastructures for play.

Video Game Storytelling Fundamentals: Setting, Power Status, Tone, and Escalation

Definitions

Narrative is a fictional universe made up a mythology of characters and settings bolstered by a story (but often a series of stories), theme, and tone.

Introduction

Budget constraints in game development often dictate the primacy of silent, visual storytelling. This entry will identify and describe the four most critical elements of said storytelling.

Overview

Alfred Hitchcock once said, "If it's a good movie, the sound could go off and the audience would still have a perfectly clear idea of what was going on." In video games, where narrative is often a secondary consideration or an after-thought to gameplay, Mr. Hitchcock's words should not only be heeded, but they should serve as primary goal for narrative designers and game writers alike.

Why though? Shouldn't the narrative be at the forefront of every gamer's attention? It should, but industry reality dictates otherwise. The typical and historical methods of unleashing story have required the use of cut scenes or cinematics, which are often met with disdain by gamers who do not want their gaming experience to be interrupted. Game developers are not necessarily the biggest fans of cinematics either, as they can be very expensive to make.

In-game narrative, such as walking through an environment while a character is talking to the player, is a semi-popular method to communicate story, but absorbing the details from characters' dialogue can often be a challenge when a gamer is focused on surviving, shooting, hacking-and-slashing, grinding, or traversing.

There are many tools in the arsenal of a writer to reveal story or at least "drip-feed" segments of it. But narrative designers cannot always rely on the conventions of cinema storytelling to tell the story of a game. There are, instead, the universal fundamentals of visual storytelling to which to turn. It is here where story silently wields its powers and infiltrates the minds of gamers without their knowing it. In fact, if one asked them what the game is about, gamers would do so handily. But if one asked them what the *story* is about, gamers often would fail to do so, even though it would probably be identical to how they would describe the game.

This is because people – no matter what walk of life from whence they came – associate story with only what is spoken or what is visually written. What they do not realize is that story can be more than that. In fact, it does not always need words communicated to an audience. (It needs words from writers communicated to designers and programmers to build, however!) The motion picture – in this case, a screen experience that progresses with a camera, either directed by a player if a game or a filmmaker if cinema – communicates so much more than words do, due to its wide visual canvas that expands with every movement of the camera.

Make no mistake: words do add more to a story experience. But there are some basics that, if missing, render a story anemic.

Setting

Setting is the simplest, most basic building block of story. Where characters find themselves is sometimes as important as the characters themselves. Because it is in these environments in which action takes place.

But action, in this context, does not refer to blowing up buildings or killing an alien species. These instances are, instead, activities.

Action, in the dramatic sense, refers to tension or conflict. And instances that explain, diffuse, or enhance tension are action. Therefore, a setting works in lock-step with action because it is these new environments in which tension rises, either through the introduction of: new characters; new difficult topography that must be traveled; or pieces of a goal or mystery that must be solved/discovered before a player can move forward.

Inherent to setting, however, are silent qualities that cue certain psychological responses. A desolate planet, for instance, communicates a sense of menace and isolation. A battlefield

communicates immediate stress, allegiances, and dogged need for survival. A city communicates lack of space or quietude, obstacles by way of bystanders, and faster pace.

It is possible that, through years of association with these environments through other media, one's instant take on them is less inherent than it is learned. Nonetheless, they carry with them certain expectations that inform a player's experience.

Power Status

Silent storytelling fails to do its job if it cannot reveal the power status of its characters through visuals. When one sees these characters for the first time, he/she often carries psychological prejudgments that compel him/her to view a character a certain way. More often than not, game developers (and cinema professionals) feed into these preconceptions. Archetypes have endured for a reason; one cannot purge from his/her collective unconscious basic, primitive physical markers.

A tall, athletically built man with a full head of hair communicates strength, leadership, and heroism no matter how outdated and unfair that notion is these days. Nathan Drake (*Uncharted* series) and Thor still sell millions of game copies and garner high box office.

Link, the legendary hero from the *Zelda* franchise, is not an exception despite his physically unimposing stature. His adventures are almost always solitary; therefore, there is no one in his immediate environment to compare him to. Indeed, facing off against a Goliath-character type happens to him all the time, but the same thing happens with Indiana Jones, Han Solo, and Nathan Drake – eventually, a hero will confront someone bigger than they are. Visually, this communicates an underdog situation and highlights the immediate life-or-death stakes of the confrontation.

A great example of visual power status comes from another medium. *Broadway Danny Rose* is an underrated classic from Woody Allen. As a D-level talent agent who represents F-level talent, Danny Rose has no respect in the entertainment world. A man of short stature, it is a wonder how he survives financially when each of his acts are nothing short of a hot mess. One day, Danny finds himself in a conundrum as he must protect his most coveted act, a washed-up singer name Lou Canova, and cover up Lou's affair with his latest mistress, Tina Vitale. Lou's career is somewhat being resurrected, and if his wife finds out he is in love with another woman, it will set him back irrevocably. Danny must secure safe passage for Tina and Lou to meet up during a big performance at Carnegie Hall. Alas, this is no small feat, as Tina, insulted by Lou's inability to break things off with his wife, wants nothing to do with him. Danny is nonetheless persistent, convinces her to reconsider for Lou's big performance, and then guides her through a series of misfortunate events (some involving the Mafia) that result in Danny and Tina falling in love. But nothing is spoken between the two about this love. When the adventure ends, Lou flourishes during his comeback moment and Tina rediscovers her affection for the once washed-up star. To pour salt on a wound, Lou then breaks off his relationship with Danny after a bigger agent poaches him.

During Thanksgiving, Danny hosts a party for his F-level clients: a stuttering ventriloquist; a glass harpist; an animal balloon maker; and others. If one pays closes attention, he/she will see that Danny is the tallest of the bunch. (The exception being an awkward spectacled comedian who sits for the majority of time during Danny's moment of adoration from his clients.) Among the Lilliputians, Danny is Gulliver. The dialogue is irrelevant; it is the visual that counts here. All the failed acts look up to their king who has the most power in a powerless world.

Tina then knocks on his door and apologizes. Danny rebuffs her and returns to celebrate with his clients. After a moment, he rushes out and finds her a block away. He reaches out for her as a gesture to return to his apartment. She follows. As they exit the frame, the camera stays on the Carnegie Deli, the setting where the film began. This distant shot captures the most romantic of gestures. Voice over is in the background. It is inconsequential; in fact, it is just noise. The reversal of Danny's power solidified. The visual says it all.

This is environmental storytelling at its finest. Power status defined at its purest level.

Tone

As briefly stated in the "Setting" section, there are certain visuals that, either through an inherent or learned association, communicate an instant psychological response. Most, if not all, of these responses are connected to tone.

An abandoned, dark subway station – as in *The Condemned II: Bloodshot* (Monolith 2008) – plays off of one's fear of the unknown. What will jump out at me at any given moment? Again – no words need to be uttered through voice over or written on screen. This environment alone shapes a player's tendencies toward fright and builds suspense.

An early 1900s dystopia filled with American naivete and hope is quickly undermined when blood paints the streets after a Pinkerton detective crosses paths with pseudo-Christian, America First zealots. *Bioshock: Infinite* (Irrational Games 2012) consistently challenges a player's sense of status quo and peace when the aerial nation-state of Columbia is gradually revealed to be a cover for White Supremacy. Everything that is pretty and peaceful is a lie. That juxtaposition of opposites communicates a tonal disconnect that is unnerving and disorienting.

Perhaps there is something inherent in the way a person processes these environments. A dark, abandoned, rotting subway station vs. a colorful, well-designed, harmonious utopia. One is immediate about its intentions to frighten; the other waits a little bit longer before revealing the moral rot underneath. In either case, the tone speaks volumes in terms of story. It sets player expectations and then either doubles down on them or evolves them only to surprise a player through a greater sense of dread and menace.

Escalation

Story often involves a seminal question: "What happens next?" These series of occurrences, however, need to be aligned with a character's emotional journey. So, if events can escalate higher and higher and there is no psychological growth of the character, then escalation is irrelevant. Aristotle's *Poetics* and Joseph Campbell's *The Power of Myth* are excellent sources of defining "plot points" or story milestones. Each work articulates a strong sense of what a character's ultimate journey should entail. Among them: recognition, reversal, catharsis (Aristotle); Call to Adventure, Refusal, and Resurrection (Campbell).

With some permutation of these concepts, a game story is often successfully weaved. Again, escalation of these is key. And again, these events can communicate story without audio or text. (A great example of this occurs in the game *Journey*, as I will explore later.)

Goals are often easily communicated through visuals alone. If one raids the beaches of Normandy and is immediately attacked, his/her immediate goal is to get out of harm's way and, most likely, kill the enemies ahead so that the attacks can stop, allowing the player to usurp the territory from the opposition.

Up ahead, there maybe a beacon or coms center that looks valuable somehow. What is inside? Either it sticks out because there is nothing like it in the territory one finds him/herself in, or its mysteriousness is too compelling to avoid. This is a medium goal.

A long-term goal will be revealed gradually, as a player progresses from one medium goal to the next. (Conquering a massive territory or prevailing over a campaign, for instance.) What the player experiences is a steady progression of hardship – or *escalating burdens* – that she/he must overcome in order to continue on. One's moving ahead amidst these circumstances shows escalation.

Why not stay put? Games do not work that way. They require moving forward in every component of design at all times. But the context and tapestry that are wrapped around these goals open the doors for more storytelling. This is part of the core progression of a game. How one fulfills this progression often requires the efforts of a writer or narrative designer to fill in what is happening in between these goals.

Again, assuming the sound is off and there is no UI text to inform a player of what is going on, a writer must identify with a game designer: (a) what the environments are ahead; (b) the sequence of events as a player travels from one

environment to the next; (c) and what happens within these sequences.

The result is story.

How These Parts Work Together

There is no better example of silent storytelling than (thatgamecompany 2012).

From the moment the game starts, a player is immediately thrust into a desolate world, a desert filled with tombstones. One wonders what happened here? And since tombstones carry with it the association of death, one must wonder whether or not that is a fate our protagonist will confront further on in the game.

Setting: Desert. Tombstones abound.

Tone: Serene yet menacing. Bright yet mysterious.

Power Status: Unknown, as the protagonist is the only one here. Unless he/she is a character that contends with the elements of the earth; in which case the protagonist is an underdog compared to the breadth of his/her surroundings.

Escalation: There is an indiscernible structure up ahead. The player has no choice but to head toward it, unless he/she wants to get lost in the vast desert filled with nothing but sand. When the player reaches the structure, he/she is empowered by a rock with a light helix that spirals from it and fleetingly envelopes the player. Immediate goal and power-up achieved.

All of this in the first 4 min of the game! Again, no words are spoken or written on screen. Yet the goals are clear, the tone is palpable, and the setting is all-encompassing. It is the power status that remains a mystery, but again, enough visual stimuli have been presented to the player where contending with the environment compromises his/her power or leaves him/her reliant upon it. In which case . . . omnipotent, the protagonist is not.

From time to time, the protagonist will encounter mysterious tall, caped figures who endow our hero with a piece of a hieroglyphic or ancient pictogram that reveals the planet's past (or possibly the player's future) in the form of a primitive, yet dynamic map. The more encounters one has with this figure, the more the map is filled out. What is more, each encounter is followed by an unlocking of a new path or chapter upon which our hero embarks.

For the first half of the game, the desert environment is pretty uniform. But then the world turns dark and soon our hero is being hunted by a floating predator that is a cross between a centipede and a frilled shark. Much later on, after the hieroglyphic becomes complete and our hero's fate is revealed, he/she must traverse up a mountain in the midst of a windy tundra. The stakes are clear: survival. And reaching the top is the presumed safe haven.

The ending is nothing short of a tragedy wrapped, ironically, in beautiful imagery. The music, while not accompanied by words, does not deliver the aforementioned elements of storytelling; nonetheless, it adds an extra layer of magic that galvanizes numerous emotional hot spots.

There is not one moment where a player does not know where they need to go, what the stakes are, what their relationship is to the environment is, and what the feeling of the world is conveying. *Journey* leverages all of the visual tools that its environment can organically convey and is, thus, a masterpiece in silent, visual storytelling.

Conclusion

Setting, tone, escalation, and power status are clearly not the only pillars of storytelling in games. Dialogue, structure, plot, and theme are important as well. But games do not often produce the full narrative package when the final product is released. It is not ideal when this happens, but it is common.

It is often the case that a narrative falls apart when the bare minimum (i.e., setting, tone, escalation, and power status) is missing or improperly defined. Simply put: structure, plot, dialogue, and theme are sufficient but not necessary for game narrative. But tone, setting, escalation, and power status are both sufficient and necessary.

And they are, mainly because a game's budget is always under scrutiny. When cuts and reductions are a result of said scrutiny, the typical targets include voice-over (a vehicle for

dialogue) and cinematics (a vehicle for structure and plot).

When a writer is hamstrung with such a limited storytelling arsenal, it is incumbent upon him or her to assure that setting, tone, escalation, and power status are injected into the narrative and at their highest level of quality at any given moment.

Video Game Trolls and Dopamine Withdrawal

Definitions

Dopamine is a chemical compound that is released in the brain to send signals to other nerve cells, including those that make possible reward- or pleasure-driven behavior. Trolls are Internet users who stalk, degrade, diminish, or abuse individual people, brands, or institutions through Internet channels including email, social media websites, and/or blogs. The act of trolling is to apply these toxic actions through said Internet channels.

Introduction

Online trolling has become a shameful practice since the early days of the Internet. However, in recent years, the actions of trolls have reached new lows that go beyond petty insults on Twitter. This article raises an unexplored possibility as to why trolls have become so excessive and extreme in their hostility.

Overview

Trolling is an unfortunate yet persistent part of Internet culture and has reared its ugly head since the early days of online service provider chat rooms and message boards. What makes the digital hostility so pervasive and effective is the Internet's anonymity. Hate is hidden behind a faceless alias, the recipe for troll prosperity. If authenticated and transparent identities were required when engaging in across-the-board online discourse, Internet etiquette would be vastly different than it is today. It would not be weaponized, or as weaponized.

Online is also an environment with a like-minded multiplication effect. One can always find other trolls who share the same opinion as he/she has and can be easily corralled to deluge someone outside their echo chamber with relentless, vicious comments.

But trolling has gone beyond the endless stream of insults on Reddit or YouTube

comments. It now involves destroying someone's reputation, livelihood, privacy, and security.

In the summer of 2014, gaming professionals like Zoe Quinn, Anita Sarkeesian, and Brianna Wu were targets of relentless harassment by gamers who took umbrage to their political views and phantom privileges. The controversy was soon to be called #GamerGate. It started after people in the gaming world ran with a rumor that Zoe Quinn had an affair with a video game journalist to gain unfair advantage (read: positive game reviews) in the industry. But the rumor was based on fiction and started by Quinn's spurned ex-boyfriend. When the truth surfaced, however, it was too late. Quinn was a target of relentless online sexist harassment, privacy violations, and death threats. Those who had mocked the harassers or defended Quinn (like Wu and Sarkeesian) quickly became targets of an aggressive, harassment campaign as well.

To this day, the flames of the controversy have not fully died out. In the spring of 2017, the cross hairs were on Allie Rose-Marie Leost, an animator on *Mass Effect: Andromeda*, who was digitally assaulted by outraged gamers for the title's perceived decline in facial animation quality. Leost was easy to identify as she listed her role on Twitter – the same platform where she subsequently received an endless stream of misogynistic vitriol. But there are other animators responsible for *Andromeda* as well, all of whom are listed on the game's credits and many of whom have Twitter accounts. Yet they were not targeted. Why Leost? Even if she were the sole employee responsible for its facial animation, does she deserve such hateful obloquy? Alas, the misogynistic legacy of #GamerGate lives on.

Why does such vicious trolling get so out of hand? Attacks on gender, sexuality, race, and religion are the inexcusable, yet common fallback for the ignorant. When trolls can neither get their way nor persuade others successfully, a quick epithet against an enemy's identity is expected.

Today, unfortunately, there are more weapons at the disposal of the ignorant. Now it is easy to gather a posse to: overwhelm Amazon, lower a game's ratings, and detrimentally affect sales; hack into one's email account and post his/her social security number or physical address on Reddit; poison one's social media reputation by posting excessive negative comments about one's work and thereby making one radioactive to prospective clients or employers; amplify attacks on all social channels and emails and flood the victim with hatred from thousands of like-minded trolls. Such great lengths to hurt someone obviously go beyond the pale of social acceptability or rationality. These actions are cartoonish, yet they are real and not isolated incidents.

To understand the depths of this commitment to hate is to understand the emotional impulses that drive someone to do such things. Is it the type of person who's attracted to trolling, or is there something that is brought out from them when he/she feels threatened? The answer could be found within addiction.

Gaming and social media are related in the sense that there are built-in mechanisms to the interactive experience that lock in one's long-term, repeat usage. These mechanisms, such as a Facebook "like" or the killing of a Nazi Zombie in a video game, are instant gratifiers and yield a dopamine release upon every tap on the screen or press of the X button. This dopamine release encourages the repetition of that act, which, in turn, increases more dopamine levels. Hence, the cycle of addiction is born, developed, perfected, and repeated.

Dopamine is the neurotransmitter that controls the brain's pleasure center. But, if dopamine is constantly being triggered during these interactions, what happens when one stops playing games or using social media? Is there withdrawal?

Consider gambling, which does not involve the ingestion of chemicals like drugs or alcohol to induce addiction (Yet, it is considered a significant addiction and is, thus, now included in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM).) A 2013 *Scientific American* article expanded the definition of traditional gambling addicts to include online gamblers as well.

That same article described what happens when gamblers are in withdrawal:

> . . . they feel physically ill, cannot sleep and shake uncontrollably – if their brain is deprived of a dopamine-stimulating substance for too long. At

the same time, neural pathways connecting the reward circuit to the prefrontal cortex weaken. Resting just above and behind the eyes, the prefrontal cortex helps people tame impulses.

In essence, gambling addicts will experience a loss of impulses once they are in withdrawal. The behavior of #GamerGate perpetrators is very much in line with the results of a loss of impulses too. Consider their:

- Using incessant profanity in social media to demean a person's gender, race, or sexuality
- Launching a targeted stream of harassing emails and social posts that occur many times a day, several days a week, for weeks to come
- Recruiting others to gang up on a victim
- Posting private data of a victim to intimidate him/her
- Encouraging people to stalk or cause physical harm to the victim
- Exacting a similar harassment campaign against a victim's loved one or relative(s)

Evil is evil, and there is no excuse for such reprehensible behavior. But it will take unconventional means to reduce the collective behavior's effect, volume, and acceleration of abuse. Right now, there is no algorithm that can fix this issue. And the web is far from being censored. But if the mental health community were to get involved in this arena, it is possible to effect positive change. Questions to answer:

If these trolls are going through interactive withdrawal when they target a victim, how can we alter the ways games and social media sites are designed?

Moreover, is the answer to taming trolls the same as it is when treating addiction? Or does the addiction never get noticed because of the ability to be anonymous on Reddit, 4chan, Twitter, etc.?

Is there a dopamine release when a troll receives an "upvote," "heart," or "like?" If so, are interactive environments, by nature, outlets for aggressive behavior for some people, even if the interactive environment is not a first-person shooter or a hack-n-slash video game? If this is the case, then how do we change the stimuli that feeds trolls so that players or social media users can experience the same fun, but the aggression does not linger on?

Conclusion

This article is not an exploration of the science behind addiction of the brain of a gamer or netizen. It is, instead, a call to action for mental health professionals to make this phenomenon a priority, so that the online community can eventually prevent trolling victimization more effectively and purge the toxic environment that has poisoned online discourse for far too long.

Accessibility in Games

Definition

Accessibility in Games: The practice of making your games playable by gamers with disabilities. This practice also serves gamers with context-dependent access issues such as slow network connections, playing in over- or underlighted environments, playing in loud environments, language barriers, temporary injuries, etc.

Introduction

With such a wide variety of genres and platforms, video games are often branded as having something for everyone (Newman 2013). At face value, this is accurate; however, when we take a closer look at accessibility, this is not always true. As Zahand (2018) puts it: "For most of the games industry, accessibility in video games is a low priority. One reason is because of a lack of awareness among developers about accessibility issues-developers who are not disabled might not be aware of the ways that they can make a title more accessible to people with disabilities or impairments."

The gaming community has not always been kind to those with vision and mobility problems (Yuan 2009), and often people have found a need to create expensive custom controllers for loved ones that struggle with fine motor skills (Bierre et al. 2005). Issues like these often go unconsidered, but some games, like *The Last of Us Part II* (developed by *Naughty Dog* and released by *Sony Interactive Entertainment* on June 19, 2020), are making larger strides to bring more options to the table without affecting gameplay.

A Brief Summary of Hardware and Software Accessibility

It is no secret that video games are becoming a large part of everyday life (Egenfeldt-Nielsen et al. 2019). The constantly growing industry provides a major way to connect with friends and strangers alike. Games can provide educational benefits, improve motor skills and reaction time, and more. However, while games can provide a vast number of benefits, they have not been exempted from societal critique. As society grows and changes, we are finding a larger need for diversity and inclusion. Often this conversation steers toward adding more women and people of color to video games and development teams, which is a very important conversation, but those with disabilities are still lacking major inclusion. There are more than 33 million gamers with disabilities just in the United States (Mut 2019). Despite this, software and hardware for people with disabilities has not been in focus for major game developers, at least not until very recently.

Over the years, there have been major attempts to modify controller design. Some controllers have improved on design, but some have just

been totally awkward on confusing. The Nintendo 64 controller, for example, is often remembered as being bulky and strange. The Xbox controller is often cited as being noninclusive because of how large and difficult to hold it has been (in contrast to the Xbox Adaptive Controller, a controller that is designed for gamers with disabilities; Stuart 2018). Some controllers have even been created for such a specific game or purpose that they are basically useless outside of their one purpose – like the Wii bowling ball. With such a large variety of controllers, one would think that finding a controller adapted for disabilities would be easy. However, when attempting to shop online for accessibility controllers, basically only one option comes up. It is specifically for the Xbox One, and it costs around $100. This seems to be a great option and major start for companies like Microsoft, but there is definitely room to improve and keep growing. There are a few other options for controllers, but none of them are on a large production level; most are player lead initiatives either hacking or modding controllers to assist their fellow gamers (some examples can be seen at Edwards 2019). This is problematic considering not everyone has the needed fine motor skills or hand function to accurately use the typical gaming controller, nor do they have the time and money to seek out elaborate custom controllers. There is certainly a market for these types of products, but it just has not been a priority for major studios. There are some studios, however, that are working to integrate accessibility into their game software to make up for a lack of hardware. In contrast to hardware options, software accessibility has made major leaps and bounds throughout the years, and not just players with disabilities are taking advantage. Subtitles are a simple, yet major option used by so many players, and up to one-third of players used one-handed settings featured in *Uncharted 4* (Stoner 2020).

The Last of Us Part II: The Most Accessible Game So Far?

Naughty Dog, the developers of *Uncharted 4*, have seen the use and need for accessibility in their games and have worked to make major developments in this area. Their most recent game, *The Last of Us Part II*, has many critics citing it as perhaps the most accessible game of all time (Molloy and Carter 2020). There are over 60 accessibility presets in the game alone as well as full control customization. According to the game's page on the official PlayStation website, the game's accessibility features are grouped under 3 main categories: vision accessibility, hearing accessibility, and motor accessibility ("Accessibility Options. . ."). The first category, vision, gives players the options of text-to-speech, high-contrast display, HUD scale, auto-targeting, traversal and combat audio cues, navigation and traversal assistance, ledge guard, enhanced listen mode, unlimited invisibility while prone, and skip puzzle option. This preset, "configures all the recommended settings designed for players who are blind or have low vision." The second preset, hearing, adds several indicators for picking up items, dodging, and awareness as well as more subtitle options and vibration cues. The complete list of these options is as follows: awareness indicators, pick-up notifications, frequent dodge prompts, subtitles, subtitle names, subtitle directions, combat variation cues, and guitar vibration cues. The hearing accessibility, "configures all the recommended settings designed for players who are deaf or hard of hearing." The last preset, for motor accessibility, adds auto-targeting, auto weapon swap, auto pick up, camera assist, navigation and traversal assistance, ledge guard, infinite breath, repeated button press, melee combos, weapon sway, and skip puzzle option. This preset, "configures all the recommended settings designed for players with a physical or mobility disability." Each preset is adjustable and made to work with each other if needed. The game also provides a one-handed mode and fully customizable controls and button mapping that work with these features as well. Additionally, more in-game features tackle other issues like magnification, motion sickness, and navigation, to name a few.

In response to The Last of Us Part II's accessibility options, one player with vision impairment broke down in tears after years of wishing for game features like the ones mentioned (Acovino

2020) which made its way into major news outlets. With so many options and considerations put into the game, it may seem like this was a huge challenge to develop. However, Takahashi (2020) points out that "Naughty Dog thanked about seven people for helping them with the design [. . .] that means it isn't a huge economic burden to think about these kinds of things."

Various previous research suggest that working with local or relevant communities can overcome many inclusive design issues in video games and other virtual environments (Mangiron et al. 2014; Bierre et al. 2005; Jahanian et al. 2018; Şengün et al. 2019; Aguado-Delgado et al. 2020). Naughty Dog is proving that it is not hard to consider their players and put in effort for everyone to enjoy their games. Moving forward, game developers should increasingly include options like these in their games, and when they do, these efforts are seemingly appreciated by the gamer communities.

Videogame Engagement: Psychological Frameworks

Definition

Answering the questions of how and why people engage with videogames or why they enjoy certain videogames more than the others has been a perennial effort in videogame studies. On the one hand, designers and developers strive to discover novel ways to make videogames more enjoyable, immersive, and gratifying. On the other hand, researchers mobilize gameplay data to cluster players into categories depending on how they engage with videogame content and explain their behavior types. One prevalent resource to explain videogame engagement behavior has been the adaptation of previous psychological theories and frameworks to the field (Boyle et al. 2012; Şengün 2016; Balkaya and Catak 2016). Typically, these theories and frameworks were developed for non-game contexts (e.g., sports, job performance, self-motivation, technology use, economic behavior, risk-taking, etc.), and they are accompanied by a readily available rich literature. In this article, several of the most-cited and most-adapted psychological theories are summarized and discussed. Although various other frameworks and player typologies emerged with contemporary videogame research and gameplay data (e.g., Bartle's player types, 1996; 2004; Lazzaro's gaming emotions, 2004; Sherry et al.'s play motivations, 2006; etc.), here specific focus is given to the psychological frameworks developed for non-game contexts first and adapted into the field later.

Introduction

Boyle et al. (2012) performed a systematic review of research on videogame engagement published between the years of 1961 and 2011. They uncovered fifty-five peer-reviewed studies which are based on empirical evidence and which focus on entertainment videogames (rather than learning or serious ones). Through their review they cite the following psychological theories as the most influential for videogame engagement research: (1) Csíkszentmihályi's (1990) Flow Theory (originally developed for explaining optimal engagement experiences with life tasks of work or leisure), (2) Deci and Ryan's (1985; Deci 1980) Self-Determination Theory (SDT, originally discussed in education, psychotherapy, work, and sports applications), (3) Uses and Gratification Theory (Schramm et al. 1961) (U&G, originally developed to explain engagement with TV and music), (4) Davis' (1989) Technology Acceptance Model (TAM, outlines the motivations for technology acceptance), and (5) the Big Five Personality Traits (John and Srivastava 1999).

The Five Most Mobilized Framework

Below are the brief descriptions and discussions of the five most mobilized psychological theories for videogame engagement research.

Flow Theory

Flow is defined as "activities in which there is a match between high challenge and high skills." (Gregory 2013, p. 177) Csíkszentmihályi (1990) describes the conditions of flow state activities that will create an engagement with everyday life as to result in happiness. Various previous research applied the flow state conditions to

media enjoyment (Sherry 2004) and gameplay experience (Sweetser and Wyeth 2005; Chen 2007; Cowley et al. 2008). These conditions can be summarized as:

- *Clear goals:* The players can easily comprehend what their goals are and what they must do to achieve them. In a videogame, there can be a certain anxiety period before the players learn what to do and how to do it. Easing this period with tutorials and/or clear user-interface designs may result in a faster transition into the flow state.
- *Immediate feedback:* The players can instantly see and understand the results of their actions. They can also track if they are doing well or not.
- *Challenges matching skills*: The players need to ascend in a learning curve that keeps challenging them as the videogame progresses. Challenges that are too high or too low compared to the skill level of the players will both frustrate them equally.
- *Deep concentration*: The tasks that are given to the players encourage attention and concentration.
- *A feeling of control*: The players need to feel in control throughout the entire gaming experience. Unjustifiably hard-to-learn or hard-to-execute controls may disrupt the experience of flow.
- *The sense of time is altered*: The players lose track of time or the time seems to pass with more rapidity.
- *The activity is intrinsically rewarding*: The experience is worth engaging in for its own sake. The videogame awards the players for their progress.

Designing a videogame harmonious with the flow state may facilitate engagement, but there is also room for alternative approaches. Experienced players may still enjoy videogames with steep learning curves (Sánchez et al. 2009), or videogames with delayed feedback or invisible control schemes can still invoke positive gameplay experiences (Şengün, 2013).

Self-Determination Theory

Self-determination theory (SDT) suggests that intrinsic motivation is the core type of motivation for sports and play (Frederick and Ryan 1995). There are three factors that support or diminish intrinsic motivation: autonomy, competence, and relatedness. These factors have been widely adapted to gameplay and gaming experiences (Ryan et al. 2006; Przybylski et al. 2010; Deterding et al. 2011).

The feeling of autonomy for playing videogames may be accepted as inherently established since the action of play seems to be always voluntary. However, in some cases, that may not be the case (Deterding 2011). Inside the gameplay experience, the sense of autonomy deepens when the players have the perception that they are free to choose what they want to do and the in-game instructions are accordingly flexible. A sense of autonomy may be established when the videogame is not overly retributive over players' actions. This enables the players to be free to go back to the parts they have failed (or even succeeded and passed) and replay these parts to get better results or to experiment on the different outcomes, rather than being forced into singular trajectories. For narrative videogames, the intrinsic motivation is expected to increase when the players can choose different paths within the storytelling and can see that their choices affect the advancement of the narrative.

A feeling of competence is created when the players are challenged optimally and receive positive feedback (Gee 2003). The concept of competence is similar to Csíkszentmihályi's flow conditions, specifically to establishing challenges that match skills. In terms of game design, planning an optimally increasing challenge arc enhances the experience of competence. Additionally, being able to acquire new skills and access new content over time may also create instant positive feedback for the player, enhancing competence and, in turn, increasing intrinsic motivation.

Relatedness is the experience individuals have when they feel connected with others (Ryan and Deci 2001). Initially, this might only be assumed as the videogame having online multiplayer aspects, yet there are other ways to create relatedness. If a videogame is not suitable for cooperative or competitive online play, it may instead offer online scoreboards where players can compare

and compete their performance. To an extent, a sense of relatedness may also be created with online message boards or other online social interaction platforms where the players of the videogame can discuss the different aspects of their experiences. As a result, even if the gameplay itself cannot offer relatedness through multiplay, the social aura created around the videogame might.

Uses and Gratification Theory

Uses and Gratification Theory (U&T) asserts that individuals seek media and media content for a variety of gratification purposes and that their choices are "purposive, goal-directed, and motivated to satisfy their social and psychological needs or desires." (Weiyan 2015, p. 77) Contemporary research constructed several adaptations of the theory to explain videogame use (Selnow 1984; Phillips et al. 1995). Most notably, Sherry and Lucas developed a U&T measurement scale for videogame use (presented in 2003 at ICA; published in 2006) and mobilized this scale to explain the effect of gender differences in videogame genre preference, usage, and play time (Lucas and Sherry 2004).

Technology Acceptance Model

Technology Acceptance Model (TAM) and the Extended Technology Acceptance Model (referred to as TAM2) (Venkatesh and Davis 2000) focus on measuring the perceived usefulness and the usage intentions of new technology by individuals. TAM2 extends the model through the constructs of social influence (the effects of social interactions on adopting or rejecting technologies) and cognitive instrumental processes (specifically job relevance, output quality, result demonstrability, and perceived ease of use).

In its adaptation to videogame engagement, several factors of TAM are offered to have precedence: ease of use and learning opportunities instead of job relevance (Bourgonjon et al. 2010), perceived mobility and perceived skills (Park et al. 2014), and social experiences (Hsu and Lu 2004). Wang and Goh (2017) provide a meta-analysis of 50 articles that mobilize TAM2 to explain videogame acceptance, and they find that "perceived ease of use (PEOU), perceived usefulness (PU), and perceived enjoyment (PE) significantly associate with attitude and behavioral intention" (p. 662).

The Big Five Personality Traits

The Big Five Personality Traits framework is one of the most mobilized psychology scales to define personality (John and Srivastava 1999). The Big Five was adapted across a wide range of disciplines from business to learning, from personal relationships to national values, and from addiction studies to videogame use. At its core, the scale defines five dimensions to quantitatively base personality on: (1) extroversion versus introversion; (2) agreeableness versus antagonism; (3) conscientiousness versus lack of direction; (4) neuroticism versus emotional stability; and (5) openness versus closedness to experience (Costa and McCrae 1992).

Various research uncovered empiric relationships between videogame use, gameplay behaviors, and the Big Five Personality Traits. For example, Witt et al. (2011) assert that extraverted and open-to-experience youth report higher levels of videogame use. In another study, being extrovert and open-to-experience were suggested as predictors of the immersive tendency in virtual environments (Weibel et al. 2010).

Latest Additions

To complement the review of Boyle et al. (2012), a purposefully limited systematic review of research on videogame engagement published between the years of 2012 and 2017 was performed for this article. Only the top 5% relevant results of the review search were used to validate that the abovementioned theories were still in use and to discover if any new frameworks gained attention in the field. The limited review results underscored the ongoing interest in adapting the five psychological frameworks to game studies; however, novel efforts to adopt additional frameworks were also uncovered.

Data Collection and Selection Criteria

The additional review was limited to research that mobilized empirical data, focused on

entertainment videogames, mobilized an existing psychological framework, and published between the years of 2012 and 2017. The search used MIT Library's BartonPlus which includes more than seventy-five academic databases (e.g., SCI, SSCI, PsycArticles, PubMed, JSTOR, EBSCOhost, arXiv, etc., among many others). The search method used is given below. This search resulted in around 12,000 results, and only the top 5% relevant results were manually scanned.

> ("computer games" OR "digital games" OR "videogames" OR "video games") AND ("motivation" OR "engagement" OR "enjoyment" OR "immersion" OR "absorption" OR "gratification") NOT ("learning" OR "education" OR "gamification")

Results

The manual analysis resulted in 31 studies using the following frameworks: SDT (27%), Flow Theory (19%), Internet Gaming Disorder Scale (13%), Social Identity Theory and Social Capital (13%), U&G (10%), Regulatory Focus Theory (6%), Social Cognitive Theory (6%), TAM (3%), and The Big Five Personality Traits (3%).

The results showed that SDT and Flow Theory were still the most mobilized psychological theory adaptations in explaining videogame engagement. Theories of Social Identity, Social Capital, and Social Cognition had diverse levels of adaptations in building and verifying scales. Two newcomer frameworks – Internet Gaming Disorder (IGD) Scale and Regulatory Focus Theory – were noteworthy additions and they are discussed below.

Internet Gaming Disorder (IGD) Scale

American Psychiatric Association's 5th edition of Diagnostic and Statistical Manual of Mental Disorders (DSM-5) introduced the Internet Gaming Disorder (IGD) Scale in 2013. IGD mobilizes the learnings from previous addiction scales and adapts them to measuring disorderly online gaming practices.

While IGD is already put to use by various studies (e.g., measuring internet gaming disorder in Taiwan by Ko et al. 2014 or in Germany by Rehbein et al. 2015), there are also critics of the scale (Király et al. 2017) especially on the vagueness of "diagnostic criteria and appropriate symptoms." (Bean et al. 2017, p. 378) In any case, the scale is likely to have more exposure and validation in the upcoming years.

Regulatory Focus Theory (Regulatory Focus and Regulatory Fit)

Regulatory Focus Theory (Higgins 1997) asserts that individual behavioral patterns and decisions are directed by personal assessment of loss and gain. According to their assessments of loss and gain, individuals develop and act on two self-regulatory orientation foci: promotion or prevention (Crowe and Higgins 1997; Higgins 2002). Individuals with promotion focus act on participation, advancement, achievement, and growth, while, individuals with prevention focus act on security, safety, and responsibility (Ozturkcan and Sengun 2016). Moreover, individuals might experience negative or positive fit with the task at hand and their self-regulatory orientation. The positive regulatory fit will increase the engagement of the individuals with the task at hand, while the negative regulatory fit will distance them (Higgins 2000, 2005; Higgins et al. 2001).

Ozturkcan and Sengun (2016) adapt regulatory fit in explaining abnormal gaming behavior in massively multiplayer online (MMO) videogames. In this example, players with promotion focus experience a regulatory fit in the beginning of the MMO gaming experience, gaining levels, skills, items, etc. in an easy and fast fashion while discovering new virtual places and adventures. However, as the videogame progresses toward the maximum level, goals become harder to achieve, requiring long hours and cooperation with a larger number of players. Discoveries also become scarce and hard to make. At this stage, promotion focus players start to experience a negative fit and find it easier to quit the videogame to move on to other experiences. For prevention focus players, the situation is opposite. At the beginning of the MMO gaming experience, prevention focus players may proceed slower since they do more research on decisions that might affect their endgame (e.g., selecting the best race or class to play; the most advantageous

adventures, skills, or items to focus on; etc.). In the endgame, they may experience a very strong positive fit, since they have accumulated virtual gains (e.g., strong characters, hard-to-find items, social capital among other players, in-game achievements, etc.) and find it harder to quit the videogame. In fact, various research underscores that addictive or compulsive gaming behavior is frequently the result of players trying to protect their in-game investments (Wan and Chiou 2006; Lu and Wang 2008; Peters and Malesky 2008).

Conclusion and Discussion

This article provides a snapshot of the efforts of adapting previous psychological theories and frameworks regarding engagement and motivation to the field of videogame studies. Flow Theory, Self-Determination Theory, Uses and Gratification Theory, Technology Acceptance Model, the Big Five Personality Traits, and Regulatory Focus Theory are identified as the psychological frameworks that were most mobilized for explaining videogame engagement. Internet Gaming Disorder (IGD) scale is an outcome of this adaptation efforts and was published as a part of DSM-5.

The main advantage of mobilizing previous psychological theories to the field is the ability to access a large body of empirical data and methodologies associated with them. However, it should also be acknowledged that adaptation into the field requires meticulous customization, validation, and novel assessments of the subject matter. Videogame designers, developers, and researcher would benefit from referring to psychological methodologies and knowledge in explaining player behavior and designing player experiences.

Virtual Hand Metaphor in Virtual Reality

Definitions

Virtual Hand Metaphor is a set of interaction techniques for selection and interaction with objects that are within reach of a user's arm. Virtual Hand Metaphor closely resembles real-life interaction with objects; the user manipulates the object directly using a virtual representation of their hand or hands. A more general term (3D interaction) includes Virtual Hand Metaphor as one of the common approaches to interaction with virtual objects in an immersive environment.

Introduction

Object selection and manipulation are basic tasks in 3D user interfaces. One way the task can be realized is through Virtual Hand Metaphor. In the spirit of natural-user interfaces (Buxton 2007), the Virtual Hand Metaphor borrows from the way users interact with real objects using their hands and adapts it for manipulation of objects presented in an immersive environment.

Types of Virtual Hand Techniques

In the Virtual Hands Metaphor, objects are acquired and manipulated in a way that closely resembles real-world touching and gasping; that is, users control a virtual hand in order to acquire,

reposition, rotate, scale, distort, or otherwise modify objects in the 3D world. Due to current technological implementations, virtual hands are usually less precise and result in slower completion of a task than alternative techniques such as Virtual Pointing. However, virtual hands provide better immersion and increase a perception of virtual body ownership. Virtual hands are usually implemented as one-to-one mapping of the user motor space (the volume of space reachable by a user's motor system, e.g., user's arm) and the control space (the volume of space reachable by a virtual hand in the immersive system).

Because of the similarity to real-life interaction, techniques based on Virtual Hand Metaphor are prone to many of the same disadvantages the interactions in the real world are; in particular, limited reach and the potential for fatigue (Bowman et al. 1999). In consequence of the focus of the HCI community on increasing performance and decreasing fatigue, only a small number of techniques based on Virtual Hand Metaphor were developed and published, as compared to the large number of techniques based on virtual pointing metaphor (Argelaguet and Andujar 2013).

Some variants of Virtual Hand Metaphor, such as Go-Go technique (Poupyrev et al. 1996), address limitations on reach. In Go-go technique, the user's motor space is not mapped one-to-one to the control space. Instead, a custom Control-Display gain function is used. This increases the reach of the virtual hand beyond the limits of user's arm length.

The problem of fatigue in using virtual hand technique for prolonged time remains unsolved. Previous studies quantify the amount of fatigue, or so called "gorilla-arm effect" (Hincapie´-Ramos et al. 2014). Keeping an arm raised for a prolonged time renders the virtual hand impractical for long-term use. Despite these results, many applications developed for consumer-grade virtual reality systems, such as Oculus Rift CV1 with Oculus Touch, utilize virtual hand metaphor as the primary mode of interaction.

Input Devices

Virtual hand requires an input device providing at least six degrees of freedom (DoFs) to correlate rotation and translation of the real and virtual hand along all three axes. Some input devices provide more degrees of freedom to simulate virtual finger movements. High-precision hand-held input devices used to implement virtual hands include magneto-optical trackers, such as Oculus Touch, HTC Vive Controller, and PlayStation Move controller. Virtual hands can also be realized as a free-hand interaction using optical hand tracking from markers-based high-precision motion capture systems, such as VICON or PhaseSpace, to low-cost markerless systems, such as Leap Motion, and

Virtual Hand Metaphor in Virtual Reality, Fig. 1 Virtual Hand Metaphor implemented for Oculus Touch, 6DoFs magneto-optical motion tracking device

Microsoft Kinect. Alternatively to optical tracking, wearable input devices may be used, including motion capture suits (e.g., Perception Neuron suit), off-the-shelf smartwatches (Pietroszek et al. 2017; Kharlamov et al. 2016), electromyographic sensor (Thalmic Myo armband), or digital gloves (Senso glove) (Fig. 1).

Conclusion

Virtual Hand Metaphor is a standard metaphor for interaction with objects in immersive systems. It allows for interaction with objects that are within the reach of user's arm length. For many interaction tasks, Virtual Hand Metaphor is slower and causes more fatigue than alternative solutions, such as Virtual Pointing Metaphor. Nevertheless, it is popular in consumer-grade virtual reality systems because it is a natural translation of a user's interaction with real-life objects, thus increasing immersion and perception of virtual body ownership.

Definition

Modern healthcare is constantly discovering and exploring the contributions that virtual reality can make to healthcare. The adoption of virtual human characters has had a success growth, in the past decades, in education, movies, games, and embodied conversational agents (ECAs). However, the growing interest of virtual reality in healthcare might stimulate a renewed interest in virtual human character. Therefore, this paper introduces the potential application areas of virtual human character (VHC) in healthcare from the point of view of realism and draws attention to the technology behind VHC as it pertains to realism.

Introduction

Modern healthcare is constantly discovering and exploring the contributions that virtual reality can make to healthcare. The usefulness of virtual reality in healthcare was discovered as far back as the 1990s during a surgery planning when a team of medical practitioners needed to visualize some complex data for a surgery (Chinnock 1994). Whenever the term "virtual reality" is used, attention is usually directed toward a three-dimensional (3D) imaginary world that allows for integration of human senses and interaction within a computer-generated environment using devices, such as head-mounted display, DataGloveTM, or a joystick (Satava 1995). However, there is the other aspect of virtual reality that is minimally discussed in literature, the virtual human character. Virtual human character (VHC) is a computer-generated human look-alike that could act as replacements for human in virtual environments. The VHC, this paper is particularly concerned with, is the one to do with the human face. The adoption of virtual human characters has had a success growth in other aspects of life, such as education, movies, games, and embodied conversational agents (ECAs).

Virtual human character as human look-alike should be able to express facial expression, facial emotions, and exhibit interaction characteristics, and these are fundamental components in achieving realism. Currently, there is a growing interest of virtual human in healthcare. Though the "uncanny valley" has in some ways slowed the focus on VHC in other application areas (Kokkinara and McDonnell 2015), in healthcare, it should never be an object of concern. The reason is this: imagine being a medical student and the virtual agent instructor lack human characteristics, will you have a committed interest and engagement during the training? Realism for virtual humans is key for such a scenario. Therefore, VHC should be developed in such a way that the "uncanny valley" effect is minimized/negligible as much as possible. Simply put, uncanny valley is human look-alike characters that lack real human emotions.

A great deal of healthcare systems requiring virtual humans needs realism to sustain the goals of virtual human adoption. A study in Seyema and Nagayama (2007) show that higher levels of animation of virtual faces are better perceived as being appealing. The question is: does this apply to all applications? This paper serves to assemble at one point the application areas of virtual humans in healthcare with emphasis on the dependency of the VHC on realism based on the application areas. Also, highlight will be thrown on current state of VHC research and technology relevant to virtual human assisted healthcare.

The rest of the paper is organized as follows. In section of "Virtual Human Application in Healthcare", the application areas in healthcare where virtual human requires realism is presented. The technology, through literatures, behind virtual human as it pertains realism are discussed in section of "Virtual Human Character Technology". In section of "Virtual Human Character Challenges" is a highlight on observable challenges of the virtual characters in realism. The conclusion is presented in the last section.

Virtual Human Application in Healthcare

Virtual human in healthcare has several applications, some of which are identified and discussed independently as listed in Magnenat-Thalmann and Thalmann (2004).

- Virtual patients for surgery and plastic surgery
- Virtual humans for treatment of social phobia and virtual psychotherapies
- Virtual teachers for distance learning, interactive assistance, and personalized instructions
- Virtual human for simulation-based learning and training

Virtual Patients for Surgery and Plastic Surgery

During surgery planning, surgeons usually simulate how a procedure will play out on a given patients face by using a simulated image of a patient. The simulation offers an avenue for the patient to build confidence in the doctor and can also help doctors understand and practice the procedure that best fits a given patient. Virtual humans are used in surgery to practice aesthetics and conduct maxillofacial surgery, oral surgeries, etc. Since the interest is more on the face of virtual humans' character, the discussions here are limited to literatures with emphasis on the face of the virtual character. The research work by Patel et al. show that high face fidelity of virtual humans helps surgery patients interact easily with VHC (Patel et al. 2013). The use of virtual humans in patient surgery is one of the oldest areas of virtual human application in healthcare (Raibert et al. 1998; Altobelli et al. 1993; Rosen et al. 1996). The study in Karaliotas (2011) used virtual patients to provide normal and pathological conditions in the simulation of human anatomy and with emphasis on realism. In Smith et al. (2005) a virtual reality model is created for simulating aesthetic surgery procedures. The adoption of virtual humans in surgery help patients know and experience what can be expected from a surgery (Khor et al. 2016). Thus, the patient and doctor can have a good understanding of successes and implications of certain procedures.

Virtual Humans for Treatment of Social Phobia and Virtual Psychotherapies

In Sjolie (2014) virtual characters are proposed as a tool for helping dementia patients and persons who are experiencing cognitive decline. However, the extent to which realism is to be attained for this use case is not yet clear. What is clear is to be able to help fight phobia among social phobic individuals requires the scene of commonly experienced social woes to be constructed to mimic real-world scenario (Didehbani et al. 2016). The scene alone is not enough; rather the manipulation of the virtual human verbal and behavioral responses is an avenue to assert control of the level of therapy measures invoked with the use of VHCs (Brinkman et al. 2008).

Anxiety is one of the medical disorders that can be medically treated through psychotherapy. The treatment process involves psychological counseling which comprises of cognitive-behavioral therapy (CBT), psychotherapy, or a combination of therapies. Pan et al. (2012) through their study showed that presenting socially anxious participants to a VHC help in dealing with situations that might trigger anxiety. The VHC does not necessarily have to be human look-alike nevertheless should be able to exhibit human facial gestures and expressions, give and maintain eye contact, and talk and interact with the human participant (Pan et al. 2012; Grillon et al. 2006).

Virtual Teachers for Distance Learning, Interactive Assistance, and Personalized Instructions

The teacher's role in a learning environment is void of learning without interaction, eye contact, exhibiting emotions, and expressing such emotions. A virtual agent should easily assume these behaviors and characteristics within a learning environment to be able to meet the expectations and acceptance of its human users.

Healthcare, particularly medical and nursing education and training, often involves the acquisition of knowledge through use of voluminous study materials which are constantly being updated, thus presenting a challenge to learning. Virtual reality has stimulated the increasing excitement on the integration of virtual humans in medical training process. According to a study on support for technology in healthcare education in 2010 Kron et al. (2010), 98% of over 200 medical students supported the inclusion of virtual teachers in healthcare training. Another study in Gromala et al. (2015) suggest that training of mindfulness meditation, a healthcare intervention program which has been used over decades to

reduce addictive behaviors, is more effective with the use of virtual humans than with humans themselves.

Virtual Human for Simulation-Based Learning and Training

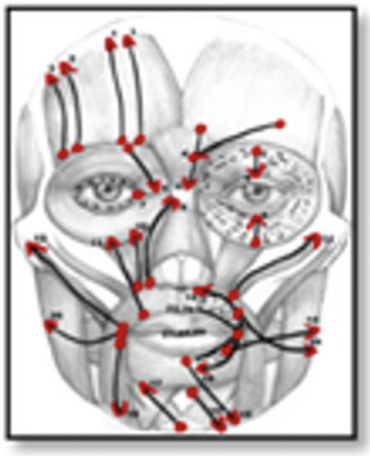
Realism has been our focus so far, but it is more heightened here because simulation-based learning and training for medical practitioners require high level of realism. Why is this the case? The simulation should mimic the real thing. For instance, imagine that virtual human suffering from internal pains (depicting a real patient; see Fig. 1) is presented as practical bed for junior doctors, the virtual human should be able to express pains when touched at various locations of the body pain is experienced. A VHC that lacks the ability to show emotions and express feelings will send across a different skill set and knowledge other than the required to the team of the junior doctors being trained. Therefore, VHC in simulation-based learning for healthcare practitioners should be able to simulate the real thing. The application of VHC for simulation-based learning and training in healthcare are endless. The study (Bertrand et al. 2010) used virtual humans to simulate hand hygiene practices for the full medical hygiene cycle: doctor, nurse, and patient. According to Zielke et al. (2010), a huge advantage of virtual humans in simulation of reality for medical education is that the learning environment and scenario of design can be adapted to simulate various levels of medical conditions; high-risk and low-incidence cases. The trainees can as well be able to learn the various factors such as patient regional, social, economic, behavioral, and cultural factors that can influence diagnosis and treatment sessions with a patient.

Virtual Human Character Technology

In the preceding session, various literatures point to the significance of realism of VHC as it pertains to healthcare. In this section, we seek the technology as identified in literatures for achieving realism for virtual humans. Therefore, the reviews of literature are based on the underlying methodologies that are currently used for VHC realism and are discussed under key topics in the succeeding subsections.

Facial Action Coding and Expression

The facial action coding system (FACS) is adversely applied for understanding virtual character model (Kopp et al. 2006). In Shapiro (2011) FACS was used to achieve virtual character simulation, control, and realism. (Čereković and Pandži 2011) employed neural networks together with a manual synthesis of face expressions, speech, and gestures with facial animation model. This work was improved by Wang et al. (2010). Their work made use of the action units (AUs) which defines 46 points on the face. These units are assumed to house the regions of the face facial muscles or group of muscles contract and reveal the face emotions. The Fig. 2 shows the



Virtual Human for Assisted Healthcare: Application and Technology, Fig. 2 Action units and main codes on the face (Morten Havmøller Laursen 2012)

simpler AUs for a typical human face. The arrows show the directions of movement of the AU, while the endpoint red arrows are the center of mass for emotion. To achieve facial expressions alongside continued human dialogue emotions, latent semantic analysis concept is adopted for embedded conversation for virtual characters (Zhang et al. 2013).

Character Deformation and the Physics Model

Facial deformation can be achieved through manipulating on element-wise basis, mesh units by some deformation functions. Multi-facial expressions can be created by combining muscles, though not the structure, and representing spline surfaces as hierarchical B-splines (Thiebaux et al. 2008). A muscle model was created by Platt and Badler in 1981 using the human facial structure and to generate multi-facial expressions; they applied the muscle arcs to flexible meshes. This approach was also adopted in (Ali et al. 2018), and the efficiency of synchronizing speech with the virtual character was evaluated using a context-dependent viseme. The observed that the number and distribution of fiduciary points effect on the quality of viseme presentation. The study in Leigh and Zee (2006) on physics muscle resulted in Greta: a virtual agent developed by Pasquariello and Pelachaud (2002) to synchronize gestures with speech to coordinate.

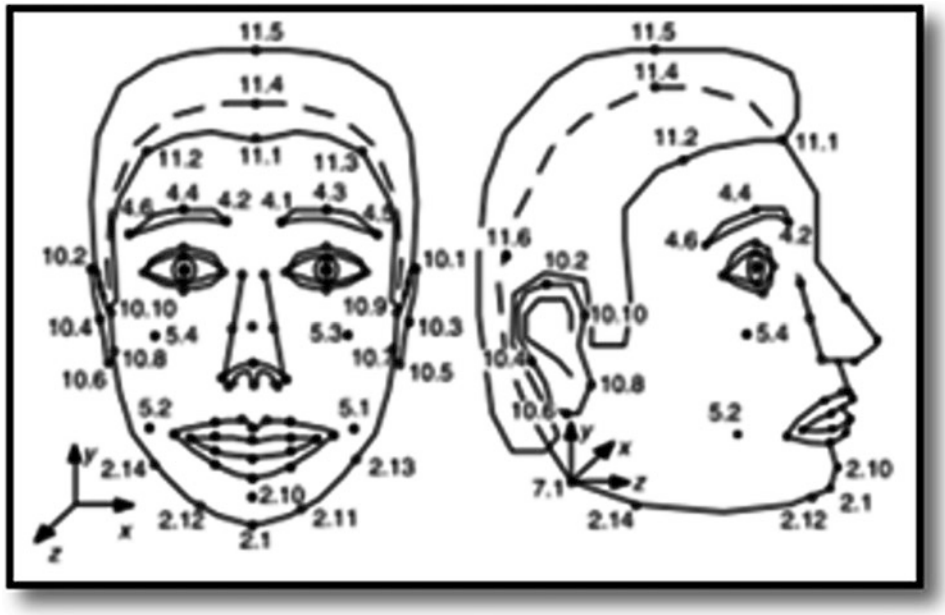
Performance-Driven Virtual Character

The performance-driven VHC is useful in circumstances where difficulties in controlling facial animation result from inaccuracies of movement tracking. This is a significant issue in real-time healthcare scenarios, especially for simulation-based training. In simulation-based training, interactivity of characters must be ensured to naturally combine motion and expressions. Deng and Neumann (2008) proposed to synthesize an expressive speech animation system through control at the phoneme level. In Hofer et al. (2008) an automatic lip-motion trajectory synthesis of the ECAs was presented. The work was extended by Zoric et al. (2011). They used animation trajectories achieving desired lip-speech synchronization with the ECA.

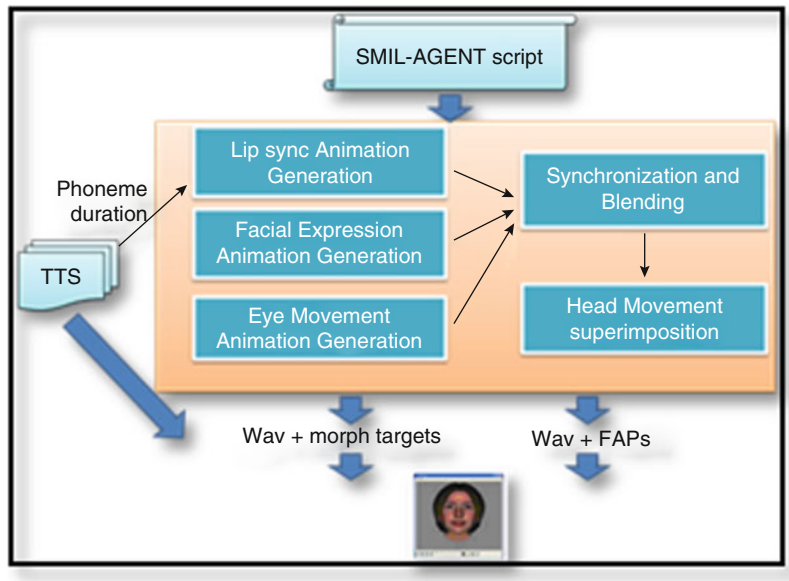
MPEG-4

Several literatures adopt the MPEG-4 technique in facial animation (Parke and Waters 2008). The MPEG-4 is used for generating animation based on three face data; face definition parameters (FDP), the face animation parameters (FAP), and the FAP Interpolation Table (FIT), which define the FAP interpolation rules. The FDP is used create 3D face geometry. The FAPs is designed to encrypt animation facial emotions, expressions, and speech pronunciation. After identifying 68 face parameters (see Fig. 3), they are animated through the face animation parameter units (FAPU). To achieve neutral facial emotion, the FAPUs are used to calculate distance between face units. Balci et al. (2007) created the Xface tool which is for the ECA using the MPEG-4 and achieved key-frame driving using the SMIL-agent scripting language. This method is visually depicted in Fig. 4. The purpose of their method is to be able to mimic human expression and emotion in the absence of gesture.

Queiroz et al. (2009) used the MPEG-4 attain parameterization of face with a high-level facial actions and behaviors of virtual characters that can interaction human user. In Zoric et al. (2011) synchronized facial gestures



Virtual Human for Assisted Healthcare: Application and Technology, Fig. 3 Some facial features points for the face as the MPEG-4 standard (Ali et al. 2018)



Virtual Human for Assisted Healthcare: Application and Technology, Fig. 4 The SMIL-Agent script processing (Balcı et al. 2007)

and speech to virtual character using MPEG-4, it lacked emotions. Their work was improved in Kessous et al. (2010). In Kessous et al. (2010) a Bayesian classifier was used to identify the different types of emotions for different gestures, which they adopted to achieve human-like character but lacked face movements. Arsov et al. (2010) developed an approach

that makes virtual character achieve interaction and learn cued speech.

Visual Speech Virtual Character

Facial expression alongside recorded speech is difficult to model. The reason is this: The human language comprises of vocabulary, phonemes, and speech coarticulation, which need to be integrated to achieve realism (Arsov et al. 2010). In Skantze and Al Moubayed (2012) the IrisTK, a toolkit designed for multiparty face-to-face interaction, while the Situation, Agent, Intention, Behavior, and Animation (SAIBA) is developed to compute ECA communication and human behavior realization (Bevacqua 2011), Berger et al. (2011) incorporated hissing and buzzing to speech synchronization with virtual character.

Virtual Human Character Challenges

The exhibition of facial expression, emotions, and interaction for VHC are not yet as good as that of a real human. However, just to avoid "uncanny valley," it is widely acceptable if the VHC can communicate all the important expressions of emotions of the human, make eye contact, and engage in interactive activities.

To simulate the emotional state of the virtual character, it is important to determine facial expressions and behavioral characteristic that the model is to mimic prior to modeling, for example, lip-syncing synthesis animation. Lip-synching has existed for decades, but the real challenge originates in blending emotions with lip-synching to produce fuller and richer character animation. For model-based talking head systems, it is more elegant to work on the facial animation parameters to bring about coarticulation effects. Giving information to a user in the form of a talking head increases acceptance level of the VHC by the humans. Therefore, the integration of speech to an animated character may also make the use experience acceptable to users, especially for social phobic patients.

During synchronization of the VHC with human emotions identified during FAP, conversation should be simulated to obtain the varying emotional states of the human model, and care should be taken to ensure that the lexicon obtained contains enough emotions variables before encoding. This is to guarantee that different personalities and dissimilar emotions required in a dialogue are captured. More also, eye movements are very important factor for achieving realism for VHC. The believability of the virtual human is not necessarily of being human look-alike but in its ability to maintain facial behaviors that mimics human behavior, such as eye contact, blinking, and squinting.

Conclusion

The future holds a great potential for VHC in healthcare. The benefits of VHC in healthcare are endless and will serve to enhance the medical practices, therapies, and education. The successes of VHC in other fields of application, such as military, games, movies, and sports gave us a glimpse of its possibilities which will continue to drive the interest of VHC developers, researchers, and the medical practitioners, who are the healthcare end users. Therefore, there lies the challenge of achieving valuable experiences, limiting "uncanny valley" effect while attaining realism, between the virtual human and various application usage scenarios in healthcare. Finally, the design features that enables the VHC to assume human behavior and character which would make virtual human in healthcare enjoyable and readily adopted is still lacking. Though, the sole purpose should not only focus on human behavior but richly capture material content as well, especially for simulating an educational instructor or surgery.

Virtual Pointing Metaphor in Virtual Reality

Definition

Virtual Pointing Metaphor is a set of interaction techniques for selection of objects that may be outside of reach of user's arm. Virtual Pointing Metaphor closely resembles real-life pointing with a finger: the user points at the object and confirms its selection with a mid-air gesture, a voice command, or a button click. Once selected, the object can be translated, scaled, rotated, distorted, or otherwise manipulated. In the context of large screen interaction, virtual pointing is often referred to as "distal pointing." A more general term, 3D pointing, includes virtual pointing metaphor as one of the common approaches to selection of objects in immersive environments.

Introduction

Object selection is a fundamental task in 3D user interfaces (Bowman et al. 2004). Most interaction tasks in immersive systems start with a selection of an object of interest. A selection technique must facilitate the indication of an object, confirmation of its selection, and should provide visual, haptic, or audio feedback during the selection task. One way a selection task can be realized is through virtual pointing metaphor. In the spirit of natural-user interfaces (Buxton 2007), the Virtual Pointing Metaphor borrows the familiar pointing

gesture from user interactions with real objects and adapts it for selection of objects presented on a large screen or in an immersive environment.

Virtual Pointing was initially developed for interaction with 2D objects presented on large displays, before it was adapted for interaction with immersive systems. One of the earliest examples of Virtual Pointing Metaphor is the demonstration entitled Put-that-there (Bolt 1980). This interaction technique combines voice input with mid-air gestures, allowing objects to be moved on a large display in front of the user. By using a combination of voice and mid-air hand gesture, the technique demonstrates how multimodal input can enhance pointing. However, "Put-that-there" technique enabled selection of 2D objects only. Selection of objects presented in virtual reality requires another degree of freedom – the depth – to reach the objects positioned at a various virtual distances from the user.

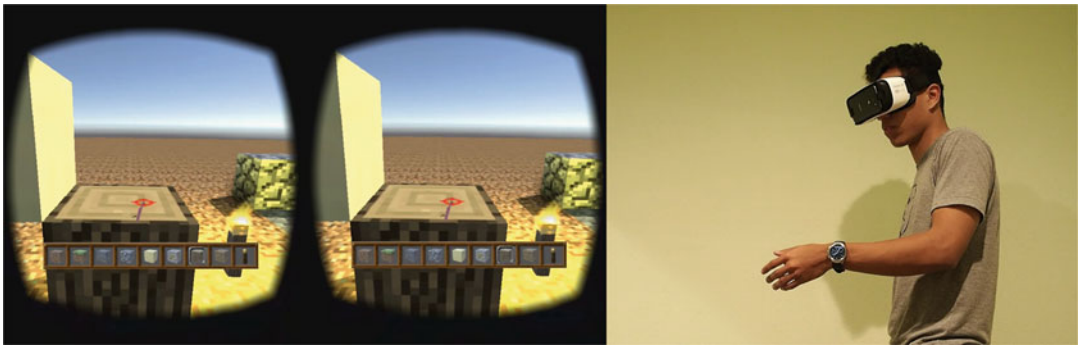
Types of Virtual Pointing Techniques

The first type of virtual pointing technique is the point cursor. The point cursor enables users to freely move a 3D point cursor (Argelaguet and Andujar 2008) within the 3D environment. The technique resembles a mouse cursor, but requires manipulation of the cursor position along the z-axis. The 3D point cursor is usually represented as a sphere or a cross-hair, rather than an arrow. The input devices position in user's motor space (the volume of space reachable by user's motor system, e.g., user's arm) is directly translated into the cursor's position in the control space (the volume of space reachable by point cursor in the virtual system). To reach the target object, the user moves the input device. The function describing how the input devices movement and rotation in the motor space translates into the selection tool movement in the control space is called Control-Display ratio (C/D ratio). C/D ratio is application specific and can be determined by the user or the system designer.

The family of Raycasting interaction techniques is another category interaction techniques that belong to virtual pointing metaphor. In Raycasting, the direction of user pointing is presented as a ray originating at the user's input device. Raycasting techniques exists in many variations (Argelaguet and Andujar 2013), developed to address various challenges in 3D interaction, such as accuracy and speed trade-off, and occlusion. The first Raycasting technique called "laser gun" was introduced by Liang and Green (1994). Common modifications of the technique include adjusting the shape of the selection cursor, or the ray. In Aperture Selection technique (Forsberg et al. 1996), user can manually adjust the selectable areas apex angle. Some techniques combine a ray with a 3D point cursor that is contained along the ray. For example, in Depth Ray and Lock Ray (Grossman and Balakrishnan 2006) from all objects intersected by the ray, the one that is closest to the 3D cursor that can move along the ray is the one that is selected. In 3D BubbleCursor (Vanacken et al. 2007), the size of the spherical cursor at the ray's end expands or shrinks automatically to reach the object closest to its center.

Input Devices

Virtual pointing requires an input device providing six degrees of freedom (DoFs) – rotation and translation along all thee axis – in order to provide user with full control over the position and rotation of the selection tool (a point cursor or a ray). High-precision hand-held input devices used to implement virtual pointing include air mouse, magnetic tracker, Oculus Touch tracker, HTC Vive Controller, and PlayStation Move controller. For casual 3D interaction, techniques utilizing a smartphone or a Wiimote were developed (Pietroszek et al. 2014, 2015). Virtual pointing can also be realized as a free-hand interaction using optical hand tracking, ranging from high-precision motion capture systems, such as VICON or PhaseSpace, to low cost systems such as Leap Motion, and Microsoft Kinect. Alternatively to optical tracking, wearable input devices may be used, including motion capture suits (e.g., Perception Neuron suit), off-the-shelf smartwatch



Virtual Pointing Metaphor in Virtual Reality, Fig. 1 TickTockRay (Kharlamov et al. 2016): An example 3D pointing technique for virtual reality using Virtual Pointing Metaphor and off-the-shelf smartwatch as an input device

(Pietroszek et al. 2017; Kharlamov et al. 2016), electromyographic sensor (Thalmic Myo), or digital gloves (Senso glove). When the input device does not provide 6 DoFs, fixed-origin virtual pointing techniques can be used as an alternative (Jota et al. 2010) (Fig. 1).

Conclusion

Virtual pointing is a standard metaphor for selection of objects in virtual reality systems. For non-occluded interactions, where target objects are not hidden behind other objects, or when the target objects are outside of reach of the user's arm, virtual pointing is also the most efficient and ergonomic pointing metaphor available.

Definition

Mixed Reality (MR) joins both physical and digital worlds, resulting in a new reality that applies the advancements in computer vision, graphical

processing, display technologies, input systems, and Cloud computing (Microsoft 2022).

With the introduction of MR, Milgram and Kishino (1994) enriched the concept of Virtuality Continuum (VC), which describes the MR gradient, having the real environment and the virtual environment on opposite sides of the spectrum, and Augmented Reality (AR) located closer to the real environment. On the other hand, Augmented Virtuality (AV) is placed closer to the virtual environment.

AR is a reality that joins the real world and actual objects with semitransparent pictures displayed with the help of a certain device. Virtual Reality (VR) is a real 3D environment created with a computer that enables the user to interact in real time with his surroundings (Yount 2004).

A robot is defined as a machine that looks similar to a living creature with the ability to move autonomously as well as perform complex actions (Merriam-Webster 2022).

Robots can seem as MR entities as they are a combination of virtual attributes like computer states and abilities. In addition, robots have a physical manifestation with which they are able to interact with the real world (Wang 2011). Robots are found in multiple shapes with different capabilities, such as humanoid and quadruped robots.

Humanoid robots physically resemble human beings with legs and arms and mimic human behavior. They are made with complex designs to enable movement in various directions. For this reason, they tend to be more expensive and difficult to build (Ben-Ari et al. 2018).

Quadruped robots have four legs, and they are usually faster and more stable than biped robots (Atique et al. 2018).

Introduction

With the rapid development of technology, many ways to combine digital and physical reality have been designed, creating Mixed Reality (MR). This term was introduced in 1994 by Paul Milgram and Fumio Kishino in their paper "A Taxonomy of Mixed Reality Visual Displays." Since then, many applications using Virtual Reality (VR) to contribute for MR experiences have been presented, incorporating a variety of elements, like robots.

Virtual Reality (VR) and Robot Development

Most robots are used for safety and manufacturing purposes. For example, Pérez et al. (2019) mentioned that some manufacturing tasks are too complex to be automated. That is why, a relationship between humans and robots on collaborative tasks was encouraged, using VR to create a virtual environment with an interface that directly associates robots with its controller.

Being used for training, Pérez et al. (2019) developed a VR environment that offers a simulation that relies on sensory inputs from the user creating a 3D environment with the intention of being fully submerged in the simulation. This was accomplished by replicating the pragmatic behavior of items.

An accurate 3D virtual representation was achieved by doing meticulous scans of the environment, including walls, objects, tools, machines, panels, pipelines, lamps, boxes, etc., and considering textures, colors, and lighting effects. It concluded that the use of virtual interfaces and scenarios to interact with industrial robots would make the most of VR capabilities creating flexible, safe, and efficient applications to enhance training and ultimately accomplish safe real-time interaction.

In addition, the use of VR is a developing tool for the construction of quadruped robots, including simulating the walking mechanics of a quadruped robot on a slope, making use of a Virtual Modeling Language (VRML), and creating a modeling scene in MATLAB to come up with a road-mapping simulation (Wang et al. 2014).

By observing the behavior of the simulation curve, the walking stability of the robot is studied to demonstrate how a displacement of the curve impacts the gravity forces applied to the robot to

displace it smoothly. The applied simulation walking elements were the following: (1) the quadruped walking is always periodic motion; and (2) the robot body must not collide with the ground (Wang et al. 2014).

The final simulation was useful to demonstrate the effectiveness of the developed non-fragile robust controller showing a greatly anticipated control performance, which is also relevant for the robot's planning and controlling walking strategy. The test carried over the simulation confirmed the viability and stability when walking on a slope (Wang et al. 2014).

More on the matter, Livatino et al. (2021) identified that most robotic systems with a wide variety of sensors allow knowing an operating robot's current status. However, the understanding and using the high amount of data provided to the operators creates a challenge, especially in the remote teleoperation of robotic vehicles. For this reason, they developed an interface using MR and visual elements to present the information within the user interface.

MR was applied to develop a design interface with an intuitive representation of the information focusing on the required elements for proper control of the vehicle to support operators while driving and retrieving sensor data using graphic elements joining stereoscopic views with head-mounted displays to improve performance reinforcing operator's situational awareness. In addition, a 3D model of the region where the robot would be operating was developed, taking into consideration the environmental geometrics of an outdoor scenario. This is interesting as most VR models map indoor premises (Livatino et al. 2021).

The proposed design included interfaces combining the following elements: single-window representation, video-synthetic images, intuitive data viewing, and regional and directional visual aids. It was tested among 12 users to get feedback on the learning experience and acceptance. The element that had a higher level of performance was the one based on VR, showing how beneficial the uses of these resources can be when testing remote-vehicle teleoperation skills and data analysis (Livatino et al. 2021).

Virtual Reality (VR) and Quadruped Representations

Moreover, on the matter of using VR, due to the COVID-19 epidemic in 2020, many museums had to close their doors to the public, causing significant economic losses. Therefore, many museums had to develop new supporting programs to remain relevant and renew the way interaction with their audiences took place. Some of them used VR technologies to enhance engagement to create distant user experiences.

One relevant example is the Smithsonian Museum, which started 3D scanning as part of its exhibit. After improving the process, it opened an online exhibition on its website portraying the scanning of most of its productions. Then, taking it to the next level, they partnered with Instagram to use the app to display a virtual representation of their artifacts in people's personal spaces using AR (Anthes 2021).

The use of VR to get people to interact with exhibits at museums is a tool that has been developed before. For example, in 2019, the American Museum of Natural History in New York City used this element to create an exposition where visitors could piece together the skeleton of a T. rex dinosaur. At the end of the exhibition, an animation of a real-life sized T. rex was projected on a screen that interacted with the people passing by, snapping them if they stuck around long enough (Gramling 2019).

Conclusion and Discussion

The possibilities that merge with MR are endless as technological tools can be implemented in many creative ways to ensure an exciting experience for the user. On the matter of joining robots and VR, it has been seen that educational and recreational approaches have already been explored. However, a lot of research is needed to properly exploit the advantages that a virtual environment can provide, for example, using it to teach robot control or enhance educational techniques, among many other applications.

Definition

Virtual Reality (VR) is a three-dimensional simulation environment where users can feel close to real life experiences in an artificial world developed with different devices and visualization equipment, as well as interacting with other objects.

Introduction

According to Gobbetti and Scaneti (1998), virtual reality is possible to create a visible world that is felt, treated, and acted on the basis of virtual reality. Similarly, Deryakulu (1999) states that virtual reality is a technology that users get different experiences from an artificial world created by computer with special technologies worn on their bodies. Sherman and Craig (2003) claim that the virtual reality environment is expressed as interactive computer simulations that allows users to immerse and simulate an environment. In the virtual reality environment, the senses act as if they perceive a physical reality (Sherman et al. 2009). Virtual reality can be characterized as either interactive or noninteractive simulation application

which is designed to create a sense of presence in a virtual world created by computer with the help of some wearable technologies and imaging equipment. Human-machine interaction in virtual reality may mislead human emotions. Dede et al. (2017) state that virtual reality focuses on visual or audio stimuli with some haptic devices and it provides sensory immersion.

Features of the Virtual Reality Environment

Three important features of virtual reality are expressed by Piemental and Teixeira (1995) as "three-dimensional graphical world," "being immersed," and "interaction." Sherman and Craig (2003) add "emotional return" to these features. According to Piemental and Teixeira (1995), the main components of virtual reality are model, computer programs, computer, location sensor, and interaction tools. Whyte (2002) states that interaction is the main feature that separates virtual reality from animation and navigation. These features are described in the following text.

Three-dimensional graphical world: Modeling of real environment or imaginary space.
Being immersed: The fact that you are mentally withdrawn from the real world.
Interaction: The response of the environment to the user's commands.
Emotional return: To be sensibly affected by the actions of the observer in the virtual environment.

In addition Burdea and Coiffet (2003) emphasize that virtual reality has three important components ("three I"). These are: immersion, interaction, and imagination. Immersion means creating the feeling of "being there" (presence); interaction means ability of the users to move in the virtual reality environment and to interact with the objects; and imagination means convincing users to believe something even if their representation is unreal.

Types of Virtual Reality

McLellan (1996) deals with types of virtual reality under nine titles. These are defined in the following text.

- *Immersive First-Person:* The user is positioned within the view. Constant interfaces and a BOOM imager are used to simulate the experience of going through virtual space. The BOOM viewer attaches to the front of the viewer.
- *Augmented Reality:* It is an information processing technology that combines real-world images with computer-generated encoded data.
- *Desktop VR:* It is the easiest one in virtual reality. The biggest disadvantage is that the user does not feel like being immersed. This reduces the feeling of being in the environment (presence).
- *Mirror World:* This system uses video cameras as input devices. The user sees his or her own image as adapted to the screen.
- *Waldo World:* In Waldo world, user is connected to real time by a remote control mechanic router. The user controls an image of the computer animation placed on a robot or image in real time by wearing an electronic mask or body suit plugged a sensor detecting movements.
- *Chamber World:* The virtual world in this environment is defined as a room surrounded by walls and ceilings. The observer enters this place and fully adapts to the virtual world by wearing three-dimensional special goggles. This interactive virtual reality environment, potentially consisting of many users, can be used effectively in collaborative projects. The CAVE system is an example of systems installed with ceilings, floors, and screens with four walls mounted.
- *Cabin Simulator Environment:* It requires environments that are connected to computers, designed in the same way as reality. It allows the real environment to reflect on the screen and to interact with the user.
- *Cyberspace:* It is possible that anything can be found anywhere and anytime in cyberspace. Any person at any point in this world can

Once attached to the head, the current image can be viewed through the optical system. The user can easily navigate around the virtual environment (Beier 2008). (**b**) *Data Glove:* The data glove is an input device which provides data entry to computer with hand movements and specific positions. (**c**) *Body Suit:* By entering these clothes equipped with special sensors, users' movements can be perceived and user movements can be transferred to digital environment. (**d**) *Spaceball:* These devices are joystick-like and can be used by pressure in desired direction. Spaceball is also used in motion analysis

be found in the same environment at the same time.

- *Telepresence/Teleoperation:* The individual feels that she/he is in a different place than the place where she/he is physically present.

Interactive Devices Used in Virtual Reality

Interactive devices used in virtual reality can vary according to their purpose. Some of these interaction devices are introduced below. Figure 1 shows some interaction devices used in virtual reality.

Some New Virtual Reality Technologies

The high cost of virtual reality devices, the limited access to facilities, requiring expertise in the adaptation into the education sector, and long-term use leading to health problems are disadvantages of virtual reality applications. Although virtual reality applications were seen as an expensive technology, virtual reality experience has been sought after and desired by everyone recently. Increased interest to virtual reality attracted attention of mobile technology companies, and this caused the development of numerous new mobile equipment and applications including components of virtual reality. Especially, by decreasing the cost of virtual reality goggles, virtual reality applications for mobile operating systems became accessible and practical. Many free downloadable virtual reality applications in Play Store or App Store, for example cheap Cardboard goggle (Fig. 2) developed by Google Company, became easily accessible for users.

Detailed information about Cardboard is available at https://www.google.com/get/cardboard/. With Cardboard applications, users can feel different experiences. This virtual reality goggle can be used for games (Fig. 3a), entertainment (Fig. 3b), nature trips (Fig. 3c), and medical training (Fig. 3d).

Virtual Reality Applications in Education, Fig. 2 Cardboard goggle

Another new trend in virtual reality is forming videos by jump camera system (Fig. 4). This technology offers to users the opportunity to watch 360° videos. Jump camera system consists of 16 camera modules placed in a circular pattern. Length of this setting and positions of these cameras were optimized to work with Jump compiler program. Jump compiler program converts video images consisting of 16 pieces to stereoscopic virtual reality videos. Thanks to its high-resolution stereoscopic vision technology nearby objects are perceived as nearby, while distant objects are perceived as far. In these devices, 3D alignment method specially developed and integrated into the system is used in order to obtain a seamless and panoramic image. Thus, the combination locations where the camera images from

each camera come together are not recognized. Designed 3D videos are equivalent to super high-resolution images at least five 4 K image. This technology is expected to reveal a new trend in cinema and gaming industry.

Another new technology "Google Spotlight Stories" interactive videos (Fig. 5) were designed by Google for smart phones. In these applications when sensors for videos located in certain regions were stimulated, video passes to the other stage through the sensors on smartphones. Each scene is part of the whole videos scenes and so continuity is provided in the video. Users can feel themselves in an interactive virtual reality scenario when they use it with Cardboard goggles. Today, while this application is supported by only some Android devices, support for numerous mobile devices has been recently expressed by the manufacturer.

Educational Uses and Potential Advantages of Virtual Reality Applications

Virtual reality applications can be found in the areas of entertainment, tourism, e-commerce, medicine, defense, construction, manufacturing, and education. Sala (2016) also mentioned virtual reality can be used in medical applications, foreign language acquisition, engineering training, education, field of architecture, and interior design. Students can conduct educational trips with virtual reality applications. Thus, they experience a sense of being there (presence), and they virtually go to and can hear voices of objects there. Virtual reality applications have been used in military education as defense and attack with support of simulation. In medical education, students can study on virtual cadavers or living human body and experience realistic situations. Students might have a chance to perform dangerous and costly experiments repeatedly in virtual realistic labs. Virtual reality can be effectively used to teach intangible concepts in mathematics, for better understanding of historical phenomena in history, or to teach surface formations in geography. It can also be used in the context of interacting with people in different countries for language teaching. Every user can see each other in same virtual environment and communicate and interact by using different virtual reality devices with the help online multiuser virtual reality applications. Three-Dimensional Virtual Worlds (3DVWs) are known as desktop virtual reality environments. 3DVWs can be used for

educational purposes in higher education as simulation, field trip, gaming, discussion, and virtual lecturing (Ghanbarzadeh and Ghapanchi 2016). Augmented reality is an extension of virtual reality. As in virtual reality, augmented reality applications are also used for educational purposes. Augmented reality applications can foster effective and efficient learning (Uluyol and Şahin 2016). These kinds of applications provide the fulfillment of effective collaborative work activities. Ip and Li (2015) state that virtual reality technology brings new opportunities and challenges to teaching and learning. In addition, virtual-reality-based learning environments incorporate instructional design for educational purposes.

There are some limitations of virtual reality. The costs of virtual reality applications are high, the accessibility is limited, and the expertise required for the education sector is troublesome. It is not easy to use for learners and technical information is needed. Fowler (2014) emphasizes that one of the challenges of virtual reality is understanding the pedagogical design and use of virtual reality systems. Further, virtual reality can lead to health problems during longtime usage (such as headache and eye pain). But these limitations can be overcome as the time passes and the following benefits of virtual reality applications in education may be embraced:

- Virtual reality may directly contribute to the development of students' complex ideas and skills (Roussou 2004).
- Virtual reality may offer personnel learning strategies and didactic paths that privilege an intuitive approach (Sala 2016).
- It may enhance motivation and learning (Dede et al. 2017).
- It may facilitate learning, support abstract concept learning, implement paradigms, support vocational training, support decision-making, support realization, and enhance learning process (Mellet-d'Huart 2009).
- It may be abstracted from external factors, allowing it to selectively focus on the information that is being studied.
- Virtual reality may provide a strong environment for students to understand the lesson.
- Virtual reality may enhance students' creativity and self-confidence.
- Virtual reality may provide facilities for learners when examining places where learners have no opportunity to explore.
- It may provide practice environments where it is not possible for students to experience it in real life.
- Learners may learn more effectively by joining as many applications as they want at their own pace.
- Learners may experience virtual reality by participating in applications independently of time and place.
- Students may have the opportunity to perform a task that requires physical effort and to explore as if in real life environments, without fatiguing at the computer.
- Because virtual reality environments require interaction and active participation, it may shift learners from passive to active.
- With virtual reality applications, the ability of students to use different virtual reality hardware may increase.
- Learners may learn by doing through self-discovery in virtual reality environments.
- Virtual reality environments may overcome the risk factors that can be encountered during real life events.
- Individuals with disabilities who have no chance to participate in experiments and learning environments may have access to learning experiences with virtual reality environments.
- With virtual reality applications, individuals who are far away and have common interests may come together for common projects and gain different experiences.

Virtual Reality as New Media

Susan Johnston
Select Services Films Inc., Los Angeles, CA, USA

Here are some of the most exciting ways in which virtual reality is new media.

Synonyms

Engagement; Experience; Immersive; New media; Real life; Real world; Virtual reality; World

Definition

Virtual Reality = A immersive computer-generated environment that incorporates auditory and visual elements. It is often interactive and it may contain sensory feedback such as haptic.
New Media = A digital form of media created, consumed, and distributed using digital devices such as computers, smartphones, and the Internet. It is often contrasted to old media such as television, radio, and print media.

Virtual Reality as New Media Is Revolutionary

Virtual reality was the favorite toy of techies and hackers looking to expand their skills and knowledge. The concept of virtual reality as a widely accessible form of media seemed quite far away, but now it is evolving to the point that it could even be used to make games on our smartphones more immersive.

Virtual reality is exciting and revolutionary. It's not only changing the way we use media but also the quality of people's lives. It's already being used in a number of different industries, from education to business and even real estate. Here

are some of the most exciting ways in which virtual reality is new media.

Smartphones

It's exciting that virtual reality has already moved from consoles to smartphones, and there is a whole line of headsets on the market already. The smartphone headsets tend to be a bit smaller than the console ones, something a little more akin to the ones that appeared in Back to the Future.

There is a huge range of apps that you can access using virtual reality, over 100 to be more precise. YouTube is one of them, allowing you to watch videos with 360-degree vision – something you may have already seen on social media advertising. There is also a range of games, from simple puzzles to ones that really show what the future of horror games and virtual reality has to offer.

Social Functions

Business functions are typically held around a table in an expensive restaurant. However, virtual reality seeks to change this. By incorporating it into social functions for business (or even leisure), you can show those you are meeting with a whole new side to you and your business.

It's easier to go through plans and documents, and it makes the whole experience much more engaging. While it could be seen as antisocial, you are all still able to communicate verbally; you just get to see more.

The Treatment of PTSD

Over eight million adults are diagnosed with PTSD each year. There are a number of causes, from childhood trauma to experiences that were had in the military. Traditionally, exposure therapy is used to treat the disorder, where patients recount and visualize their traumas in an attempt to treat it and remove the trauma.

Virtual reality uses the same form of treatment, but it offers a more realistic and visual world. The scenarios are played out on the screen, immersing the patient. They are then asked to narrate what is happening. The patient is able to stop at any time, just like in regular therapy.

Immersive Gaming

Becoming lost in our video games is one of the great escapes from reality. With the evolution of virtual reality, it is possible to become completely absorbed. The game surrounds you, and you are able to use your body to control the mechanics of the game. In many ways, it is becoming the new Nintendo 3DS or 3D TV – a mass market for new and exciting content.

So much is and can become accessible through the virtual reality systems, and it has the power to present you with everything at your fingertips, from video games that surround you and use all of your senses to access to your favorite streaming apps for watching movies and amusing online videos. The possibilities have the potential to be endless.

The Next Steps

In the future of virtual reality, we can be sure to see an increase of realism in the graphics produced for video games that use it. Much like regular console games have become more photo-realistic; virtual reality ones will likely follow in their footsteps. Along with this, there is likely to be increased interactivity, and research is already being carried out to see how this can be improved for future releases.

The continued development of content that is interesting is also something that has to be continued and constantly improved on. In terms of smartphone apps and video games, people are going to tire of the same content, and so more must be added, and it must be more interesting than the ones that came before it. Virtual reality is done gaining trust and acceptance; now it needs to start evolving.

In terms of new media, it has the potential to become one of the most used pieces of technology (New Media Film Festival). With applications in just about every industry and field (from business to medical training) (Applications of Virtual Reality), it really is the definition of new media. The future of virtual reality is incredibly bright as long as developers continue to work on

this new piece of tech and listen to the feedback they receive.

Virtual Reality Exercise and Rehabilitation

Jon Ram Bruun-Pedersen
Department of Architecture, Design & Media Technology, Aalborg University Copenhagen, Copenhagen, Denmark

Synonyms

Exercise; Exergaming; Virtual reality; VR rehabilitation

Definitions

Virtual reality (VR) can be described as "a high-end user-computer interface that involves real-time simulation and interactions through multiple sensorial channels" (Burdea and Coiffet 2003). *Exercise* should be understood as planned physical activity, from the intention of either increased fitness or other health benefits, as opposed to the expression *physical activity*, which is to be understood as simply movement involving muscle contraction (Landi et al. 2010). *Exergaming* is an activity with games constructed around physical activity or exercise as a facilitating part of the gameplay mechanic (Wüest et al. 2014). *Rehabilitation* can be defined as "the restoration of form and function, following illness or injury" (Hoenig et al. 1997) and "restoration of an individual's capability to achieve the fullest possible life compatible with his abilities and disabilities" (Hoenig et al. 1997). VR exercise and VR rehabilitation are to be understood as any exercise or rehabilitation activities that involve VR to facilitate its purpose.

Introduction

Lots of aerobic exercise involves motion and movement across larger areas (cycling, running, skiing, etc.), and several forms of exercise are

performed in a specific environment (strength conditioning in a gym, soccer play at the pitch, etc.). The exercise environment is therefore a part of the exercise experience for many practitioners, and can become an identifier of that exercise, and can be part of what motivates a user toward the exercise activity (Gladwell et al. 2013).

Many can (theoretically) perform most exercise types, while others are limited by certain factors: specific geographical or environmental requirements, such as skiing; human physical limitations, such as periods of temporary injury; or more permanent conditions, as, for example, physical or cognitive decline with old age, permanent injury, or innate physical handicaps. These individual factors can prevent practitioners from entering the natural environment of many exercise activities. Meanwhile, virtual reality (VR) has shown to be useful in this relation, by its convincing ability to simulate aspects of real experiences in the virtual domain, experienced in some regards as if being transported to a place that convincingly appears as if it exists. This refers to one of the most defining features of VR, which is commonly referred to as the sense of presence.

The sense of presence, as described by Slater et al. (2010), is when a user responds to the experience of a virtual environment – and treats the virtual reality, as if it was real. To experience a sense of presence, there are two orthogonal components to consider (Slater 2009). The experience of being situated in the virtual environment (VE) is referred to by Slater as the place illusion (PI) (Slater 2009). Part of the PI comes from how VR may allow users to carry out actions as they would in real life and interact with the VE or virtual objects in it. The experience of a VE may also elicit user reactions or responses as they would be expected in real life (dodging while passing a branch) or experience that the VE reacts convincingly to them being in it (such as a virtual bird dodging the user). This is referred to by Slater as the plausibility illusion (Psi) (Slater 2009). An additional key component to experiencing presence is the perception of having a body inside the VE. Seeing how a body (be it your own in a cave or a virtual when using a HMD) integrates and interacts with the virtual world plays a central part in the realness of the experience (Slater et al. 2010). In this way, VR can allow users to convincingly experience places, which are out of their immediate reach (such as a wood workshop, where there is none in real reality). Or find themselves in situations which they may otherwise be secluded from (sitting at the bottom of the Pacific Ocean). VEs can also enable users to perform certain actions that are not possible in the immediately available real-world environment (e.g., building a chair in the virtual wood workshop) or even actions that would simply be impossible in real life (e.g., unassisted levitation).

VR is a potentially powerful mediation tool for both exercise and rehabilitation. The ability of VR to place (just about) any virtual context to a real-world situation or augment the experience of a real-world activity by altering the VE feedback to that action can manipulate a big part of the user's experience and redirect attention to where it is considered most useful. A virtual augmentation of an activity can amplify the impact of positive actions or remove attention from unwanted aspects. If a user considers the real-world environment demotivating for their exercise routine, an alternative virtual environment can be created, which caters to the users' motivation or the desire to exercise. If a user does not find a repetitive rehabilitation routine stimulating (lifting a 0.5 kg weight 100 times), have the VE react to each lift in a way, which effectively augments the user's experience of the activity into something completely different. The format of the virtual environments and the augmentations depends on a lot of factors, such as the user demographic, exercise or rehabilitation type, available hardware/software, etc. The following sections will address some of the ways in which VR has been utilized for exercise or rehabilitation purposes.

VR Exercise

Mood benefits affiliated with regular exercise, such as enjoyment, energy, and reduced tiredness, have shown to be enhanced when exercising using VR, to a level surpassing regular exercise (Plante et al. 2003). Similar results have been recorded

when pairing VR with biking exercise, for instance, with elderly users at nursing homes (Bruun-Pedersen et al. 2016b), which allowed the elderly to experience nature-based VEs while on an indoor exercise bike. Results showed an increase in interest and enjoyment of the activity, when measuring the intrinsic motivating to exercise. The results were based on (a) residents' enjoyment of the VE nature settings and (b) how the augmentation gave purpose to resident's biking actions (i.e., changing the perceived value of the actions). In their particular everyday life, no residents were able to bike, and very few residents were able to leave the nursing home to enjoy nature (Bruun-Pedersen et al. 2016b). VR's potential as an exercise motivator also shows as a result of the users' sense of presence and the immersive properties of the system: immersion referring to the degree of sensory stimulation perceived from the mediating technology displaying the VE (Slater 2009). Ijsselsteijn et al. showed that the increase of the immersive properties and increases in the sense of presence resulted in positive effects on exercise motivation (IJsselsteijn et al. 2006), also the case for elderly users (Bruun-Pedersen et al. 2016a). Besides its potential as an exercise motivator, VR has also shown affinity as a training tool for exercise-related skills. Rauter et al. have shown how a rowing machine, with a high-fidelity VR simulation of a rowing experience, was able to enable a transfer of rowing skills from the VR machine onto rowing sessions in the real world (Rauter et al. 2013).

VR Rehabilitation

Even if VR is a relatively new technological tool for rehabilitation and therapy, it has diverse applications (Rizzo et al. 2015). Exposure therapy in VR has been able to induce similar emotional responses with users as in reality and used in psychotherapy for the treatment of phobia, etc. (Carvalho et al. 2010). Stroke rehabilitation using VR is showing an increasing body of work (Corbetta et al. 2015), for instance, in relation to balance training (Gheorghe et al. 2015), but also VR for analgesia (for instance, in relation to burn wound treatment) has been shown to have real effects (Malloy and Milling 2010). Physical therapy rehabilitation treats problematic conditions with regular practice of controlled movement treatment, specific to the injury. These are often performed indoors in controlled clinical environment (Hoenig et al. 1997), but users and therapists may find themselves secluded from what would naturally be the optimal environment for the rehabilitation practices (Rizzo et al. 2015). For sports rehabilitation, this has shown to cause negative effects on patients' "treatment acceptability," from the sense of detachment to the context and practice which the rehabilitation should eventually enable (Brewer et al. 1994). One way to counteract negative treatment acceptability has been mental exercises including goal setting, counseling, and visualization of the end result (Brewer et al. 1994). For sports practitioners, such mental exercises naturally relate to sports scenarios and have shown to build a more purpose-oriented connection between the rehabilitation procedures and its goal (Brewer et al. 1994). Meanwhile, VR's potential to contextualize exercise activities or actions of a user is a huge leap forward from the mental exercises (Bruin et al. 2010). VR and multimodal feedback can either take users' attention away or place users' attention specifically on certain aspects of the activity or user behavior (Bisson et al. 2007) (Burdea and Coiffet 2003), onto where it is most relevant for the user experience (Holden and Todorov 2002), while being able to digitally monitor the movements from sensors and software (Rizzo et al. 2015). Certain movements critical for rehabilitation can also be guided or paced through the VE or amplified in case the user experience needs increased awareness (Rizzo et al. 2015).

However, for practitioners with more permanent conditions, where constant rehabilitation (or light exercise) is needed to remain healthy, the exercise actions often lack a direct pointer to any context or natural environment outside the clinical practice. For such rehabilitation regiments, augmenting, e.g., a monotonous exercise experience with a dynamic and extraordinary exercise environment in VR, might counteract

repetition that creates boredom, providing what can be described as "a shift from negative to positive thoughts about exercise" (Bruin et al. 2010).

Immersive VR Exergaming

Exergaming refers to the activity of playing a game which has physical activity or exercise as part of the gameplay mechanic (Oh and Yang 2010), with Konami's *Dance Dance Revolution* (DDR) as one of the frequently referenced (Smith et al. 2009). The exercise-inducing part of exergaming comes from an engaging gameplay element, which requires motion control input from the user, and typically does so in a fast-paced fashion. For well-crafted exergames, such as DDR, this results in an exercise-motivating gameplay experience for many users.

The motion control design of some exergames is catered to certain needs, such as gameplay for balance training (Wüest et al. 2014) or physical fitness (Konstantinidis et al. 2016) and aerobic exercise for older adults (Smith et al. 2009).

For exercise motivation purposes, it would be logical to consider the potential for combining exergaming and immersive VR. And it can be argued that the concepts of immersive VR and exergaming can be naturally connected, for instance, by their implicit need for unconventional and movement-based control schemes. Martel and Muldner argue that proper control scheme design is essential to a VR experience and impacts player experience, performance, and sense of presence (as defined by Slater) and must be considered carefully according to its intended context (Martel and Muldner 2017). Conventional control methods using keyboard and mouse pose similar problems for exergames and VR applications alike, possibly breaking exercise sequences or similarly hindering a sense of presence in the VE, in order to push buttons. In fact, one of the potentially big advantages for the combination of exergaming in immersive VR would be the merge between the contextualization of the user's actions (e.g., simulating a real-world situation fitting for the exercise actions), gameplay elements, the motion controls with (ideally) any relevant body part, and the immersive aspects of the system.

Meanwhile, this may also be what partly limits immersive VR exergaming as a genre. Shaw et al. suggest the five main challenges currently faced by exergaming (Shaw et al. 2015). And to a large extent, these mirror the challenges the VR industry faces in general: (a) motion sickness, (b) accurate motion controls, (c) appropriate view for the player, (d) health and safety risks from motion controls while wearing a HMD, and (e) feedback latency (Shaw et al. 2015). None of the points are trivial to work with in isolation, and the combination remains quite complex at this stage.

Perhaps as a result of this, only few immersive VR exergames are currently released (to the knowledge of this author). "Astrojumper" uses a three-wall stereoscopic projection setup for an immersive experience, where the player uses his/her limbs to throw green laser beams and fight a UFO attack (Finkelstein et al. 2011). Lately, more commercial products (such as BOXVR for the Oculus Rift) are surfacing, using the Oculus Touch controller for virtual hand movement in various boxing-related games. The VirZOOM bike controller has users pedal and steer under various (gaming) circumstances in VR, including simultaneously riding and catching horses with lasso or (pedal) racing an F1 car. Meanwhile, current VR exergames remain very simple. They appear premature in both gameplay and production, when considering contemporary games and VR applications, and this might remain, until the challenges from Shaw become more properly addressed.

Future Challenges

Perhaps due to the relative novelty of the technology, the definitions of which role VR has in a therapy context are seeing debate, from both a practical and a terminological perspective, for instance, discussing whether VR therapy can be called therapy if "VR technology" is not

autonomously performing therapy and rehabilitation (Levac and Galvin 2013). Similarly, the patient-therapist interaction with VR technology is novel in many cases (Christensen and Holte 2017). Patients (e.g., elderly) without previous experience with VR might not elicit confidence in the technology as a trustworthy, therapeutic device. Meanwhile, Ijsselsteijn et al. argue that precisely older adults are receptive to new technology, provided they understand the benefits of the technology for their individual purpose (Ijsselsteijn et al. 2007). Part of the patients' belief and understanding depends on the level of proficiency and confidence in the system by the therapist (Levac and Galvin 2013). Moreover, the therapist also needs to be able to naturally incorporate the VR application into the rehabilitation procedures, as with any other therapeutic practice (Christensen and Holte 2017).

Using VR for rehabilitation may be a daunting paradigm shift for some therapists and a natural step forward for others. It is mainly up to the collaboration between researchers/developers and therapists/patients to document and enable the method as well as possible.

Definitions

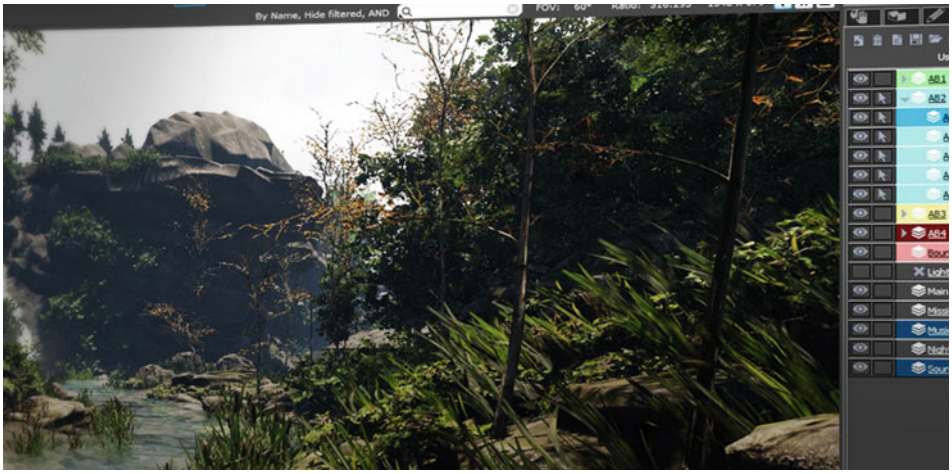
With virtual reality use cases and applications booming in the entertainment industry, filmmakers, producers and game developers alike are jumping on the bandwagon of sourcing out for the most applicable, useful and at times open-source tools for their specific virtual reality development needs. While popular brands Unity and Unreal Engine dominate the virtual and augmented reality development scene, alternatives and upcoming game engines are equally prevalent as options for game developers and virtual reality enthusiasts to explore and build their projects upon.

Introduction

Different Types of Virtual Reality

Ever since the acquisition of the virtual reality (VR) startup Oculus by Facebook in 2014, VR has experienced a comeback like no other, with various types of digital output becoming classified as VR. However, much like anything else when it comes to technology and reality, even virtual reality and its niches fall on a spectrum. Today's VR use cases have been broad; from a fully-immersive virtual reality experience rendered and viewed through the lens of a virtual reality headset (tethered or standalone devices) to an actual immersive room – otherwise known as the cave automatic virtual environment (CAVE) – virtual reality is broad as it is narrow in terms of its users, market appeal, and output. VR is currently popular in the video games and entertainment industry, alongside architectural visualizations and military simulations (the latter having been around even before 2014), either as a passive substitution of the user's environment – as in watching an immersive film – or an interactive and experiential tool for users, much like a video game or remote operating system that allows users to communicate in virtual space.

This entry will focus on exploring the multitude of game engine options available for virtual reality developers when it comes to creating



Virtual Reality Game Engines, Fig. 1 Snapshot of the CryEngine game engine interface

interactive or gamified virtual reality experiences and projects.

Virtual Reality in Games

The most commonplace use case for VR has always been in the gaming industry, and it is no surprise that gaming takes the forefront of such developments due to the industry's natural disposition to be more risk-inclined and experimental. Since the inception of VR into the gaming world, new niches and definitions of what it means to be gaming have also been formed. The term comes to mean more than just entertainment and the alleviation of boredom, to the exploration of new senses, sights, and sounds in an immersive interactive environment.

At this point of writing this entry, the two of the most common game engines being used for VR game development purposes are Unity and the Unreal Engine game engines. This entry will attempt to shed some light on other options for the purpose of gaining a more comprehensive overview of all options and tools that are available for any developer's use. The analysis would simply be a broad cross-comparison between these options for beginners and enthusiasts willing to explore these options.

Alternate Game Engines

CryEngine V

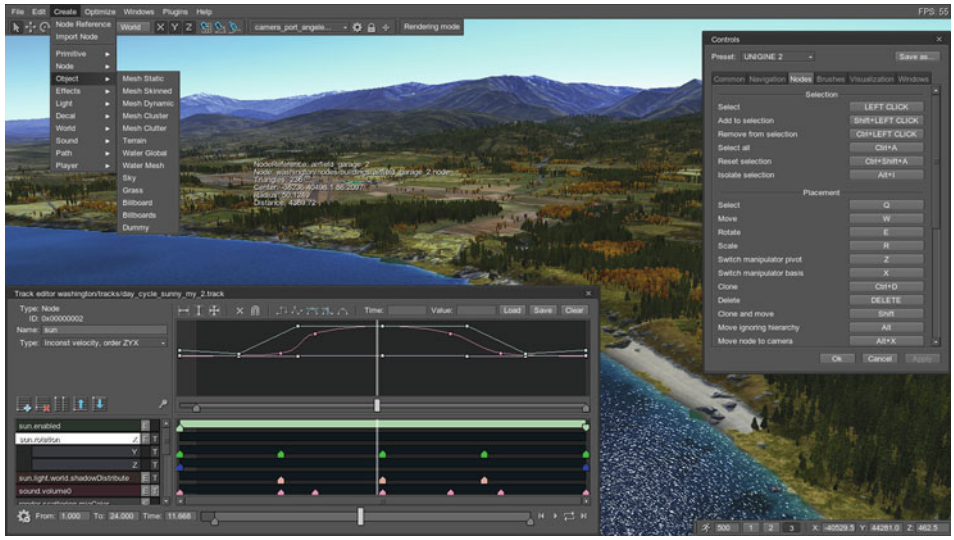
For the developers or enthusiasts hailing directly from the gaming development world, CryEngine is no stranger to anyone and has a huge pre-built following for its released CryEngine V game engine based on the fact that Crytek (the company) already has a strong base of existing users. Given that notion, it is expected that they would most likely have more developer support, tutorials, and features (Fig. 1).

CryEngine V – Cost

Since the release of this game engine under the "Pay What You Want" revenue model, the game engine is absolutely free, if the user chooses it to be so, but donations are also possible if desired. If one would like additional training, consulting services and access to more accelerated learning, one would expect to pay for and select between different tiers of CryEngine's Insider Membership packages.

CryEngine V – Pros

- Much like Unity and Unreal, CryEngine V also has a marketplace for developers to access thousands of assets and exchange them between members of the community.



Virtual Reality Game Engines, Fig. 2 Snapshot of the Unigine game engine interface

- As a VR game engine, it supports PlayStation VR, OSVR, HTC Vive, and Oculus Rift – almost every major VR hardware out there.
- Reasonable amounts of documentation (at least as much as it could offer for VR development at this point) and some support from the community (active and up-to-date) – though expect less activity than Unity and Unreal
- GPU-based particles and cloud systems (less impact on the developer's CPU).
- Contains about 75+ official tutorials on how to use the game engine.
- Games developed with CryEngine are 100% royalty-free, regardless of profits.

CryEngine V – Cons

- Apart from its official tutorials, there is limited external support and tutorials on CryEngine that is up-to-date as it would require time to accumulate the amount of support since its initial launch in 2016.
- Comparatively less users and developers to Unity and Unreal, which would likely result in less solutions and answers to be found for programming or development issues due to the smaller pool of users.

CryEngine V – Interesting Notes

It is both C#- and C++ – friendly. One would have to create a project first before downloading the game engine. They also have an initiative known as "VR First" to encourage academic institutions to create VR labs on their campuses – this is a good option to consider, for faculty members of institutions seeking to expand beyond the standardized tools of Unity and Unreal.

Unigine

Known as the professional VR platform for business, there are rarely any interface snapshots of Unigine let alone buzz or discussion about its use and how the game engine works. Mainly designed for business-to-business (B2B) markets and for industrial visualizations, and traditional virtual reality systems and use cases like scientific research and military simulations, it is possible that this game engine has had such a low profile that most developers have never heard of it, and thus never considered this option. Either way, here is a quick overview of what the Unigine game engine entails (Fig. 2).

Unigine – Cost

To get started with Unigine, one might begin with the free trial or pay the cost of the "Starter Single"

package. It is assumed that the cost of the "Sim" package would be about the cost of the individual license, plus. Regardless, all demos could be requested. Much like anything else, the more expensive the package, the more available support for one's projects.

Unigine – Pros

- One of their claims is that they offer support beyond VR to other types of immersive output as well – including CAVE systems (basically a VR system that is physically built like a cave) and curved screens.
- For B2B, it offers lots of technical support that seems to be highly customized and personalized to the business' needs – this is good for individualized attention to one's own business needs.
- Based on the visuals and screenshots on their site, they appear to have the systems capable of delivering on their promise of highly realistic VR and experiences.

Unigine – Cons

- A downside is the B2B nature of Unigine, which might also shed some light as to why most of its information is secured and locked off from public eyes.
- Less active of a community and forum – a developer's best bet for answers is going to be directly from the professional team themselves.
- Thus far, it would appear that they only have Oculus Rift support – depending on one's business, this might or might not be sufficient (checking back in for updates on any additional hardware support might be necessary).

Unigine – Interesting Notes

Their authorized distributors come mainly from Asia but they have a sales office in the United States. Due to the nature of the company and product, Unigine could potentially contain some elements that might be overlooked due to its B2B nature and highly secured information.

Fabric Engine

Somewhat of an oddball, Fabric Engine emphasizes its easy-to-use nature for artists, in-betweeners, and programmers alike using a visual programming system similar to that offered by Unreal Engine. Formed by a technical team in Canada, they go beyond just support for Fabric Engine, to include external 3D software tutorials as well.

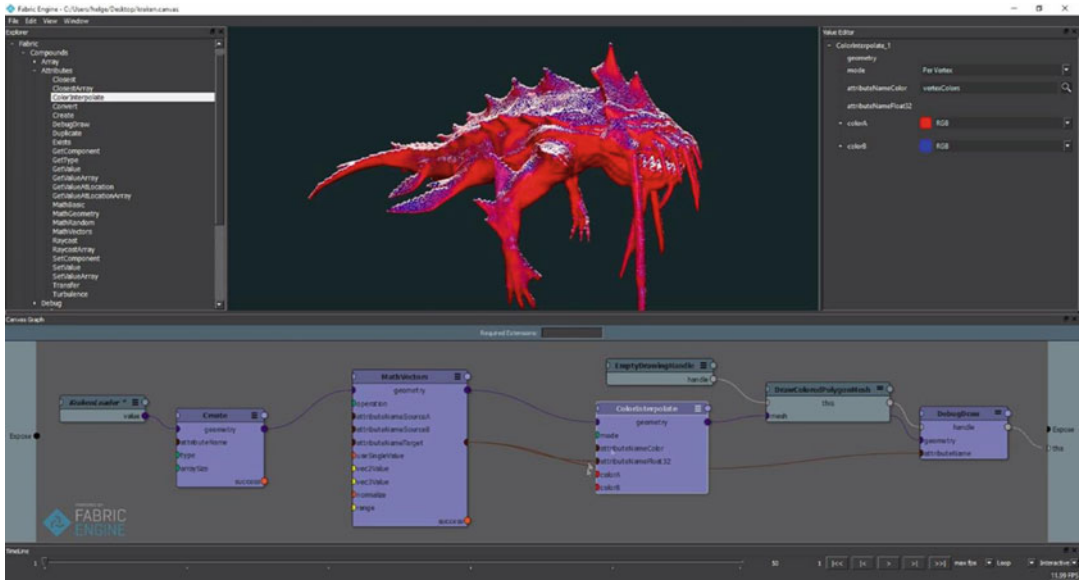
There was a downloadable version of the Fabric Engine, which held a certain degree of promise due to its node-based interface (similar to that of the Unreal Engine) and its clean layout. Unfortunately, as of this entry, their game engine is no longer being developed (Fig. 3).

Fabric Engine – Cost

Prior to the cessation of the Fabric Engine, an individual license would have cost (there was no free trial), with an extra fee to be paid for support and maintenance within the first year of purchase. If one were to rent the use or license of the game engine, that cost drops down significantly to a number more affordable to the independent game developer or user. They also offer studio and team packages at higher costs, with the possibility of a negotiable "Unlimited" package including an unlimited number of licenses. An educational license is available but one has to go through their request form.

Fabric Engine – Pros

- A massive collection of official tutorials on the engine, and even on other non-Fabric Engine related tools, are available.
- Technical documentations including step-by-step guide – telling developers exactly which and what buttons to push, with visuals, verbatim. It also tells one why that step or button has to be pushed, which helps to shorten the learning curve tremendously.
- Uses an entirely different programming language known as KL. KL has some features that optimizes memory, multithreading among other aspects, that C++ lacks or fails in comparison.



Virtual Reality Game Engines, Fig. 3 Snapshot of the Fabric Engine game engine interface

- It supports HTC Vive, Oculus Rift, Leap Motion, and Razer Hydra – quite a broad range of options.

Fabric Engine – Cons

- As with an independent or non-mainstream game engine, they have less of an active support community among fellow developers; however, it does not mean that their support from staff is any lesser in quality.
- Uses an entirely different programming language known as KL but it can call C or C++ libraries – depending on the skills of the developer, this can be a massive con.
- VR integration could still be improved.
- They are no longer in development as of the writing of this entry.

Fabric Engine – Interesting Notes

The company, Fabric Software Inc., was founded by a very technical team, which might explain some of its software features among other aspects. However, the reason it is in this list is that this might have been a potentially worthy game engine to explore had it still been in development. Major visual effects studios such as MPC and Psyop uses Fabric Engine for their film and television projects, which gives this game engine the industry validation and endorsement coming from major players of the visual effects industry.

Current Developments and the Future

Amazon Sumerian and Others

As with any technology, software or hardware, it develops quickly and changes rapidly. Since the writing of this entry comparing these alternate game engines, there have been new developments in the field resulting in other tools or software that could be useful to game developers in virtual reality.

One such example would be Amazon's Sumerian and Lumberyard software. Amazon Sumerian, launched in late 2017 for preview and experimenting, completely bypasses the programming and development process – further democratizing VR development accessibility by allowing even nonprogrammers and users with no background or experience in development or graphics generation to partake in creating their own VR, augmented reality (AR) and 3D applications and projects. With its addition of libraries of 3D characters and models, as well as its claim

to be able to run on multiple VR platforms such as the Oculus Rift, HTC Vive, and mobile, Amazon Sumerian is poised to upstage Unity and Unreal in terms of being more easily accessible and usable to the everyday person.

Amazon Lumberyard (launched in 2016), a more advanced tool in comparison, is the more serious version of Sumerian as well as an actual game engine where similar tools found in both Unity and Unreal Engine are available – including a node graph, timeline, and all other necessary features typically found in any other game engine. Their ties to gaming communities such as Twitch and Amazon's own strong web infrastructure are deliberate to allow game developers to not only develop games but also transition to and capitalize on distribution and potential showcase efforts of their VR projects thereafter.

Conclusion

Game Engine Selections

Ultimately, it depends on one's personal preference as to the software to be used in VR development for games. Given the heavy focus on VR and AR development today, one has many options to choose from, with game engines as optimized and customized for all kinds of interactive project development, including use cases such as 3D projects, games, and even live-action. The possibilities are endless and developers are definitely spoiled for choice. To avoid analysis paralysis, one should always focus on the mission and intention of the VR project.

Definition

Virtual reality facilitates a more comprehensive stage for conveying knowledge. By immersing an individual into an ultra-realistic setting, a user is able to learn about a subject by living it rather than only hearing about the topic.

Introduction

Virtual reality (VR), traditionally used in gaming, is moving into more mainstream activities and developing in focused areas such as healthcare (Sik-Lanyi 2017), for example, to help hospital patients and support training of hospital staff. Sector-based organizations are starting to recognize the benefits that VR offers toward improving the productivity of their services. As such, the main idea behind this article is to build a virtual reality proton beam therapy unit to support cancer patients undertaking proton beam therapy and, in doing so, improve the productivity of the treatment process.

According to Cancer Research UK, one in two people born after 1960 will be diagnosed with some form of cancer during their lifetime (Cancer Research UK Press Release). Children (usually classed as ages 0–16 in the UK National Health Service) make up for 1% of cancer cases in the UK, with 1 in 500 children being diagnosed each year, equating to 1,800 new child-cases per year (Cancer Research UK Press Release). The two new proton therapy centers in the UK allow for the treatment of different types of cancers. The proton beam treatment involves laying on a bed/platform inside a large spherical machine for a prolonged period. Radiation is directed directly toward the tumor cells to destroy them. It is particularly a beneficial approach for treating children. The technique moves away from the traditional cornerstone radiotherapy approach, which risks destroying surrounding tissue to the cancerous cells producing further illness and nausea. Yet, despite the benefits offered by the proton therapy units, cancer treatment is still an overwhelming process. Children are generally allocated 2-hour time slots to receive the treatment; but often this time is spent encouraging an understandably scared child to enter the large machine for treatment and remain still. The time spent encouraging the child often means that the treatment time is lost due to the child's refusal to enter the machine or that the whole treatment process is missed for that session. Therefore, developing virtual reality applications that can support cancer patients, particularly young children, is beneficial to both the patient and the hospital. The ambition behind this work is that children between the ages of 3 and 11 use the application to be adequately mentally prepared for the treatment process.

The VR development process involved in undertaking this case study requires that we work with a building information model (BIM) of a proton therapy unit. As such, a pipeline of the BIM to VR process is also outlined in this article alongside the development of the application.

Development Pipeline

Based on a BIM model, the features of the proton beam therapy unit VR application are created with the help of Unreal Engine. In the game mode, the user is able to navigate the scene and carry a panda teddy bear in their hand and it around the room. The pipeline for the construction process is outlined.

Pipeline

The VR development follows three stages: (1) BIM construction, (2) 3D model optimization, and (3) game engine implementation. This would be a typical pipeline for a BIM to VR model in an industrial setting, as outlined in the pipeline displayed in Fig. 1.

BIM Process

The BIM process is complex and involves multiple stages to refine the model through the use of hardware and software tools. BIM is concerned with the construction of every aspect of the built asset into a highly detailed 3D model recreation of the real-world object or building. It is a process which is frequently used to recreate real-world buildings and 3D models of urban environments

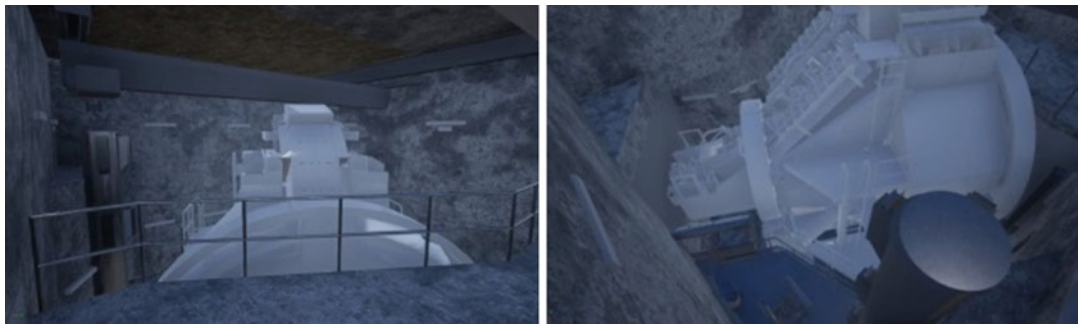
but can also be used to model the digital elevation of terrain. Typically, BIM models are constructed from point cloud data. Point cloud data is created using 3D scanners. Its application is being increasingly used in the artifact reconstruction domain (Gonzalez-Delgado et al. 2014; Cosido et al. 2015). The main challenge involved with the BIM model construction is that it results in a highly detailed model. For example, the BIM model used in this project is comprised of close to five million polygons, as displayed in Table 1. This is unsuitable for VR deployment, as the polygon count prevents the animation/game from rendering at a playable speed.

Optimization

The optimization process governs the refinement of the model into a format and polygon count size that is suitable for deployment into a game engine for VR.

For example, the BIM proton treatment unit model is comprised of thousands of individual models and details that are not needed to be present in the final VR application and can therefore be removed. Users of the application only need to see the main therapy room, therefore superfluous models (such as the rear gantry or pipework) are removed. Figure 2 displays the rear gantry, stairs, and engineer access of the proton treatment machine, which is removed during the optimization process. The optimization process can be laborious. The procedure is done by hand and requires that the model be checked through in details for removal of the superfluous 3D models. In some cases simple pipe constructions are comprised of up to 300,000 polygons. Similarly,



Virtual Reality Proton Beam Therapy Unit: Case Study on the Development, Fig. 2 Gantry and rear stair case, removed from 3D model

Virtual Reality Proton Beam Therapy Unit: Case Study on the Development, Fig. 3 Low poly-render of the proton therapy unit treatment room

chairs, tables, and screens consist of thousands of polygons per model. Each object and model within the scene is either replaced by remodeling the object to an object with a much smaller polygon count or removed completely from the scene. Figure 3 displays the low poly-interior of the scene following the optimization process.

Game Engine

The VR application is developed with Unreal Engine and can be played either through haptic interaction, such as keyboard/mouse, or by the use of a stereoscopic viewing device such as a HTC VIVE (Fig. 4).

Using Unreal Engine 4, the .FBX model is imported into the project, allowing it to be placed into the in-game world. Here it is possible to add convex collision to the model to constrain the user to a given area and provide them with a navigable experience, without the risk of them clipping or falling through the environment. When a model is imported from an Autodesk package, Unreal identifies that there is either several meshes within the file that have individual textures or when a mesh has several textures applied to it – this is referred to as "elements." Elements allow the developer to create materials either based on given textures within the model or procedurally create new materials using Unreal's material editor to produce high-quality visuals. Unreal provides developers with a wide array of standard player components, which allow for the developer to quickly create player characters to allow the player to navigate the environment with. The standard player character includes capsule component to provide the player pawn with a collision volume, a camera

component to allow the player to view the world from the pawns perspective, a mesh component to give the pawn an identity, and a movement component to allow players to navigate the virtual world with the pawn. Once development is complete, the game is packaged, which involves creating a staging folder, specifying any blueprints or levels to package, and then compiling it all into

a single executable application. The final render is displayed in Figs. 5 and 6.

Definitions

Virtual reality retailing (VRR) refers to the interactive virtual experiences that a retailer provides for its customers by the aid of virtual reality applications.

Introduction to VR

Virtual reality (VR) consists of immersing an individual in an imagined or replicated virtual three-dimensional world that provides ques on multiple sensory levels.

VR History and Early Examples

Despite the concept has been around since early 1960s, it took some time for VR to take attention from the public. Morton Heiling was the first to take action in exploiting the possibilities in moviemaking with his patented *Sensorama* that included a vibrating seat with a scent emitter to provide a richer 3D film experience (Drummond et al. 2014).

Contemporary VR Market

However, it was not until virtual reality company Oculus was bought by Facebook in 2014 for $2 billion that the VR finally started to attract the long-deserved attention (Solomon 2014). Moreover, predictions about VR market range from $30 billion by year 2020 to $45 billion by year 2025 (Li 2016; McKone et al. 2016; Weinswig 2016).

Virtual Reality Retailing (VRR) Market

Retailing is amongst the sectors that lead the expected high growth. Virtual reality retailing (VRR) is expected to reach some 32 million users in retailing by year 2025 (Bellini et al. 2016) with its anticipated applications either in-store or out-of-store (McKone et al. 2016) depending on physical presence of the customer.

VRR Examples

Some early adoptions of virtual reality retailing involve the virtual house tour by the luxury

home auctioneer Sotheby's (Bellini et al. 2016); the virtual viewing experience of appliances, paint, patio furniture, tools, flooring, and home décor by Lowes for redecoration; the virtual outdoor sporting experience by recreation brand North Face (Li 2016); virtual kitchen viewing as well as gamified store openings by IKEA (PYMNTS 2017a); virtual car showroom experience by Volvo (Robertson 2015); virtual furniture viewing by e-retailer Wayfair; virtual property preview for incoming guests by Airbnb (PYMNTS 2017b), shopping for virtual objects by Swarovski (PYMNTS 2017a) with payments enabled by Mastercard (PYMNTS 2017c), enhanced e-shopping experience by Alibaba (CNBC 2016) . Some retailers are believed to complement their stores with VRR to benefit from the attractiveness of sci-fi effect.

Key Concepts of VR Crucial to the VRR Success

VR often features common elements in offering an immersed virtual experience (Zhu et al. 2017). Head-mounted displays (HMDs) that are similar to snorkeling goggles in shape and size to restrict the wearer's field of vision only to the screen involved in the glasses are the most common element. This is followed by some platform that would run the video content on HDM. Computers, smart devices, tablets, and game consoles could be named among these platforms. And lastly, the dynamic experience in the virtual world is possible through some input from the individual by head tracking or controllers. A major challenge for VRRs is to provide an easy to use, brand-relevant, frank experience for their consumer by the aid of these common elements (Vrechopoulos et al. 2009).

Prior to the developments of The Foundry's Nuke CARA VR interface and plugins as well as Adobe's increased developments and integration with third-party tools today for live-action virtual reality postproduction, stereoscopic virtual reality was considered a difficult undertaking for independent virtual reality filmmakers and artists alike to achieve due to costs, lagging postproduction tools, or the issues that came with stereoscopic virtual reality filmmaking with stereoscopic camera equipment. Virtual reality stereoscopic post-conversion in the most easily-accessible postproduction software After Effects was necessary as a first step for complete beginners to the virtual reality filmmaking world to easily follow a step-by-step postproduction workflow to convert their monoscopic virtual reality footage from a simple virtual reality camera rig to stereoscopic 3D virtual reality footage.

Introduction

Different Types of Virtual Reality

Ever since the acquisition of the virtual reality (VR) startup Oculus by Facebook in 2014, VR has experienced a comeback like no other, with various types of digital output becoming classified as VR. However, much like anything else when it comes to technology and reality, even virtual reality and its niches fall on a spectrum. Today's VR use cases have been broad; from a fully-immersive virtual reality experience rendered and viewed through the lens of a virtual reality headset (tethered or standalone devices) to an actual immersive room – otherwise known as the cave automatic virtual environment (CAVE) – virtual reality is broad as it is narrow in terms of its users, market appeal and output. VR is currently popular in the video games and entertainment industry, alongside architectural visualizations and military simulations (the latter having been around even before 2014), either as a passive substitution of the user's environment – as in watching an immersive film – or an interactive and experiential tool for users, much like a video game or remote operating system that allows users to communicate in virtual space.

This entry will focus on exploring the passive form of VR that is live-action virtual reality and the production and rendering of panoramic videos, an art form more commonly referred to as cinematic virtual reality.

Shooting Stereoscopic VR

Prior to the software and tools we have available today that can easily work with the increasingly-accessible customizable VR camera rigs for both stereoscopic (stereo) and flat (nonstereoscopic) virtual reality footage, during the earlier years of the second rising of virtual reality back in 2015, these tools were nonexistent. Perhaps even today, these tools are out of reach to the everyday filmmaker and VR enthusiast who wishes to explore the live-action VR medium in stereoscopic 3D.

While it does ease the process of postproduction and editing when capturing footage using a stereoscopic VR camera rig such as that of the Google Jump VR camera rig, the footage would still require manual adjustments and fixes in postproduction. These fixes include the need to address broken depth due to unexpected stitching results in postproduction or even the complete upheaval and restitching and compositing of certain segments of the footage. Usually, this process of restitching and compositing of patches of corrected stereo footage would require high amounts of processing, rendering, and wait times

that could severely delay the independent filmmaker's workflow and production pipeline.

Postproduction Stereoscopic Conversion

One could anticipate that by the time that this entry has been published, newer tools, techniques, and technology will have been released to counter the workflow that is to be discussed in this entry, but the purpose of this workflow process outlined is not to tout its viability in lasting through the highly iterative and constantly changeable nature of technology per se but to serve as an option for independent filmmakers who are looking to get into virtual reality, with little to no budget – as well as the enthusiastic developer who might be able to take this process one step beyond how it presently works.

This pipeline was first established and implemented at a virtual reality startup the author was involved in, during their early days where the only tool they had at their disposal that they knew how to use was the Adobe Creative Suite. Not only does postproduction stereo conversion offer a more democratized alternative to the hardware and software solutions presently available, but it also gives the independent VR filmmaker more control over the look of their stereo VR footage – a feature that is normally irreversibly baked into captured stereo VR footage.

The images and snapshots used in this entry are taken from the company's publicly-released reel and the shot is not the property of the author – they are merely used for the illustration of the postproduction workflow of stereo conversion for VR.

The Workflow

STEP 1: Cleanup Seams

Beginning with the obvious – one would first need to cleanup the stitched output. In fact, before one even does any stereoscopic conversion, all of the VR panoramics (panos) should already be polished, cleaned, fine-stitched, and composited to remove all artifacts and seams. As one could tell from the above image, there are no seams or artifacts whatsoever, and that is the ideal starting image you would want to use to begin your stereoscopic post-conversion work (Fig. 1).

In order to cleanup the seams, an artist could accomplish this either in After Effects, Photoshop, or a combination of both. If the artist is a high-skilled compositor, Nuke or a node-based compositing software would be in the artist's arsenal of tools; for everyone else, this workflow will be outlined using After Effects.

Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 1 Final output of a clean, artifacts-less VR panoramic still frame

STEP 2: Import Fine-Stitched (Clean) Output into After Effects

Import the shot into one's compositing software of choice.

Ideally, if the artist has access to this software, one would want to use The Foundry's Nuke as it is more suitable for stereoscopic compositing, editing, and conversion (not considering its current availability of tools and plugins for VR compositing).

STEP 3: Intense Rotoscoping

The purpose of rotoscoping (or commonly known as "masking" or "roto" for short) is to isolate and create the layers of stereo depth one wishes to add into the scene. Alternatively, the more masks used, the cleaner and more polished the roto is, as one would have more control over certain areas of the character or element in the shot. In this example, the lady is being separated from the background, which will be treated as a separate layer in z-depth (third dimensional depth and space). The additional masks over the strands of hair are mainly to have a more polished and controlled roto of the character (Fig. 2).

This will be the most time-consuming part of all of VR stereoscopic post-conversion, next to waiting for the renders of any VR stereo panoramic image.

STEP 4: Clean-Plating

Stereo post-conversion creates artifacts as it now creates empty spaces or gaps in a shot that began as a flat monoscopic image.

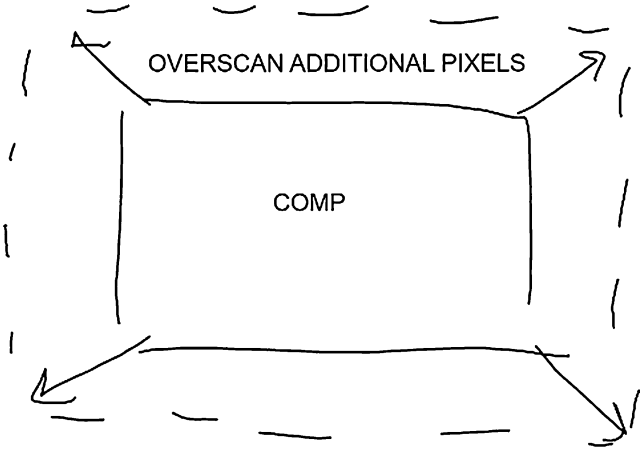
To address this, different and multiple layers of clean-plating would be necessary to fill those gaps (Fig. 3).

The quick sketch above shows the concept of clean plating – the idea of which is to extend or contract portions of the footage or film plate that would then conceal those stereo artifacts.

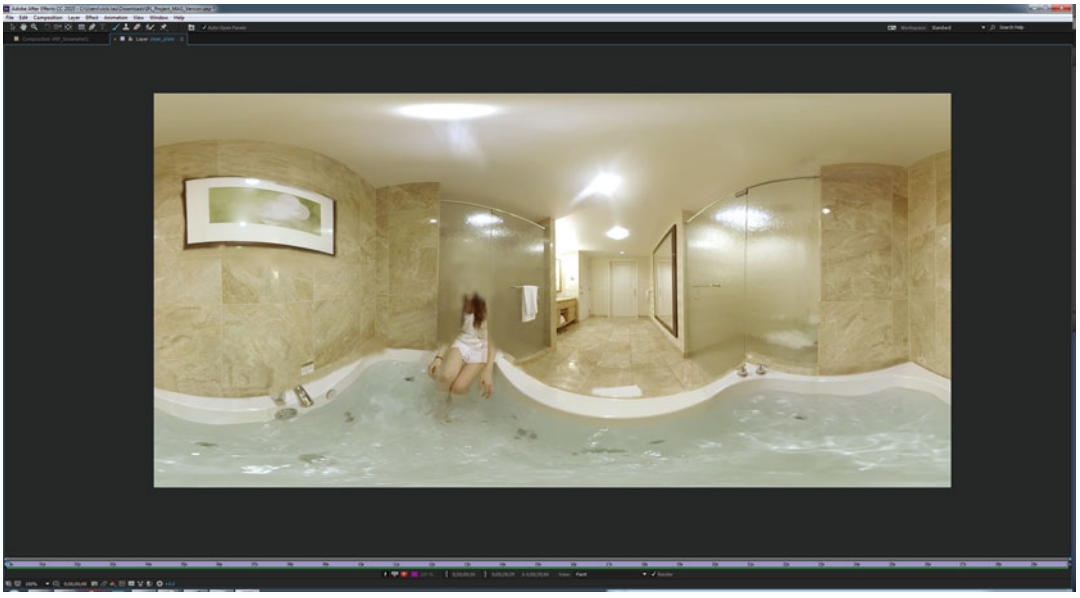
Ideally, one would have shot a clean plate (with no actors, moving elements or anything of that sort) but if this is not an option (or forgotten), a clean plate would have to be created.

To capture a clean plate on-set, one would essentially leave the camera rig rolling for about 30–60 s (longer if there are any active or moving background elements) to capture a "clean plate"

Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 2 VR panoramic work-in-progress showing rotoscoping progress



Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 3 Illustration of the creation of additional pixels of leeway for clean plating



Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 4 VR panoramic clean plate example

(no actors, no animals, preferably no moving elements) of the set (Figs. 4 and 5).

Depending on how many layers of stereo depth the filmmaker desires, one would have different finishing levels of clean plates in terms of the areas that would have extended or contracted when they were first created in the artist's design editing software of choice. In this example, the plan was to separate the bath tub and the picture frame on the wall; thus, the clean plate was contracted by painting in its surrounding pixels.

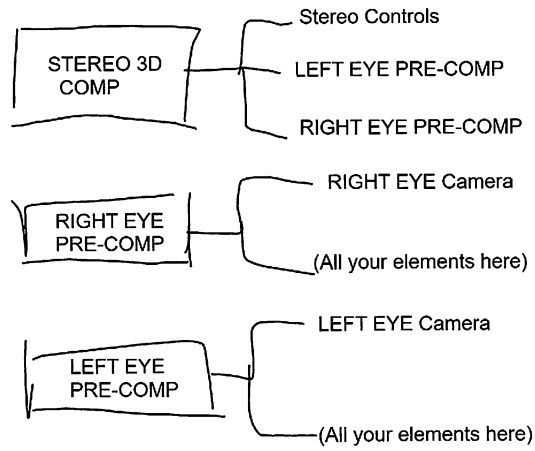
It is important to note that the deeper and more exaggerated the intended stereo depth effect, the more paint work and clean plate extension or contraction one would require to pull off the effect.

STEP 5: Precomps and Layering

The purpose of precompositions (precomps) is to ensure that the shot's depth layers do not leak into other layers. Invariably, this step could be implemented at any point in time during the VR

Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 5 VR panoramic work-in-progress showing the clean-plating contraction progress

stereo conversion process even after the stereo 3D rig has been set up; to avoid doing double work, precomps are best set up at this step of the process. Essentially, one would create a precomp (parented with other rotoscoped elements or not) of each layer of element to be stacked and layered in z-depth and space; in this case, the precomps or parented layers would be as follows: girl in tub, picture frame, and background (Fig. 6).



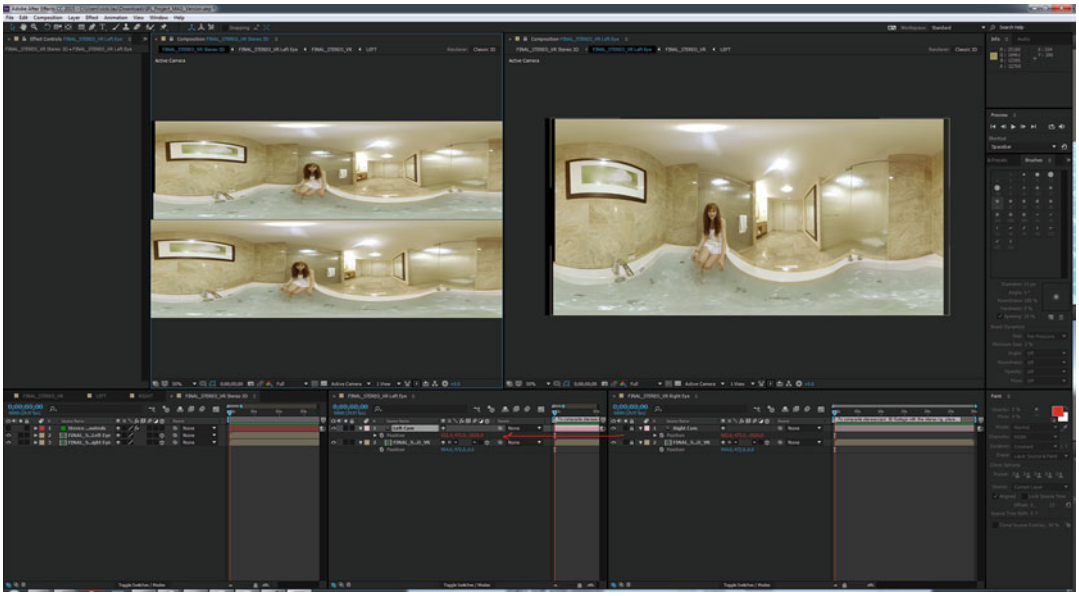
Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 6 Illustration of the hierarchy of precompositions in After Effects to simulate stereo depth

STEP 6: Create Stereo Camera Rig

After the completion of the rotoscoping process, creation of necessary clean plates, and layering of elements in z-depth accordingly, one would then proceed to create a stereo camera rig (a packaged plug-in that comes with After Effects by default). This can be found in After Effects via the following menu items: Layer → Camera → Create Stereo 3D Rig. Once created, this would open up stereo control tools for the artist to handle the amount of stereoscopic convergence and distance one would like to have in the scene. One would have to experiment with the values in Stereo Scene Depth, Convergence Z Offset, and Scene Convergence on a shot-by-shot basis as this solution has to be adapted to each shot creatively, depending on the stereoscopic effect intended (Fig. 7).

The Master Cam layer generated by the Stereo 3D Rig in After Effects is not necessary and hence deleting that will not be an issue.

One would want to ensure, however, that the 3D View is set to "Over Under", and that a split-



Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 7 VR panoramic work-in-progress showing the implementation of the After Effects stereo camera rig

screen workspace has been set up as seen in the image above – ideally outputting to a stereo external monitor (in full resolution) in order to interactively review any real-time results on the screen (whilst wearing polarized glasses).

STEP 7: 3D Layers and Depth Stacking

Setting this up is only the first step – one would now dive into one of the precomps (recommendation is to start working in the precomp for the stereo "Left Eye") and start blocking out the elements in z-depth. To prevent double work, one can parent or link the position values from the pre-comp for the stereo "Right Eye" to its respective layer elements in the stereo "Left Eye," such that any elements adjusted in z-depth would move simultaneously in both right and left eye precomps (Figs. 8 and 9).

The sketch above is a top-down 3D view of what these layers might look like with depth stacking.

The designated red area would be the furthest stereo depth layer (in this case, the room/background) while the other layers are pulled to the front to make them "pop" off the default convergence plane of the background (Fig. 10).

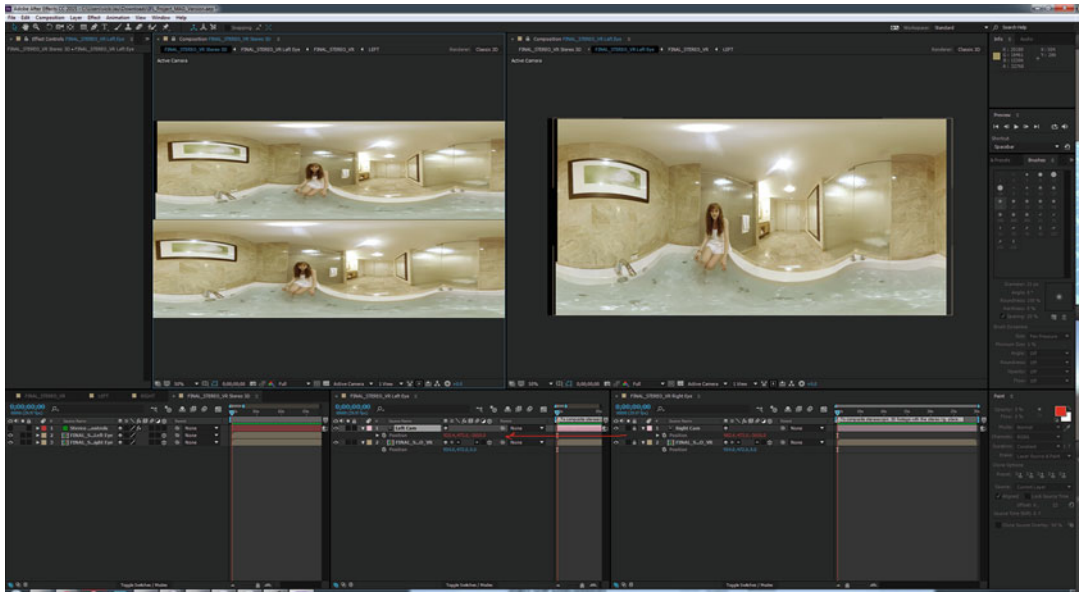
In After Effects, the more negative the z-position values, the more it tears off the screen. The more stylized and heavy the intended stereo effect is, the more work is involved in the creation of the clean plates.

STEP 8: Prepare for Oculus or Gear VR Output

This is the final step before exporting the "over-under" stereo composition (comp) to be played back in the VR device of choice. However, depending on the amount of convergence set in the existing composition, one would notice two bars of black in both the "Left Eye" and "Right Eye" comps (Fig. 11).

There are many ways to address this – either by cheating the scale or having an overscanned and extended clean plate of the background in place. For simplicity's sake, one might consider cheating the scale in its width. To prevent the disproportionate outcome, one could play around with the entire composition's scale itself to counter the altered aspect ratio.

Once that is done, simply export the highest level (main composition) of the "Stereo 3D Comp" in the appropriate format and that should be it. Take note that the export doesn't have to be a

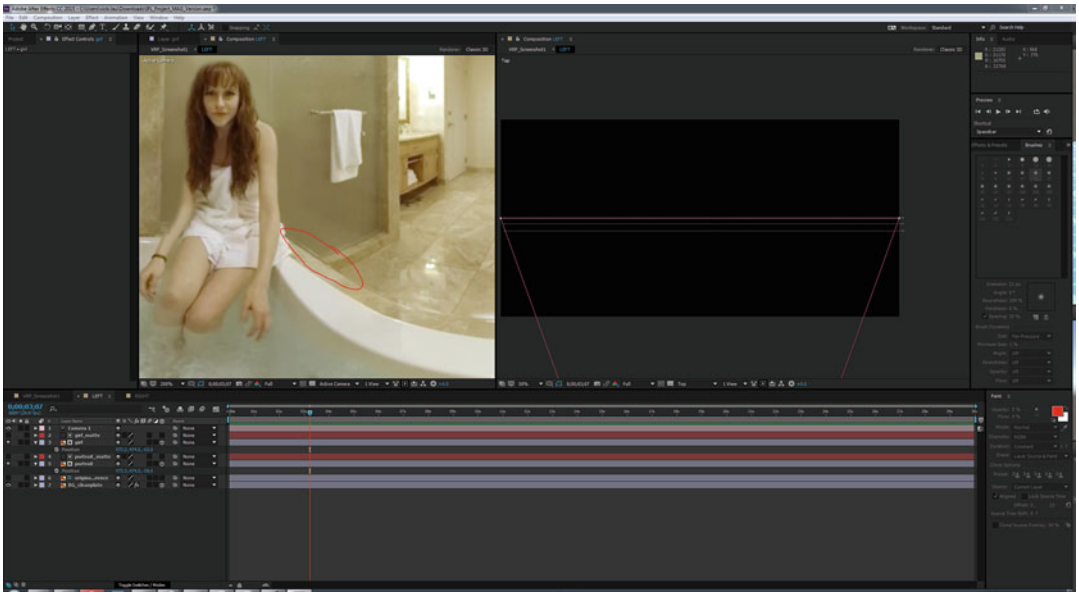


Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 8 VR panoramic work-in-progress showing the stereoscopic workspace layout

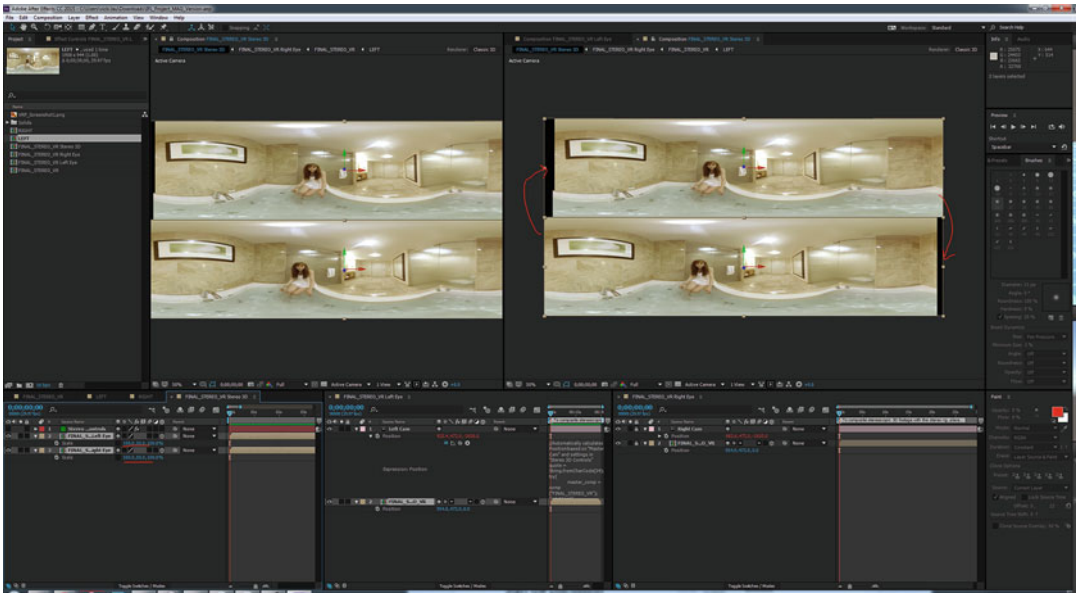
Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 9 Illustration of the hierarchy of precompositions in After Effects to simulate stereo depth

2 K by 2 K square, as it has been tested that the pixel qualitative differences between a 2 K by 2 K export and a 2 K by 1 K export would not be discernible enough to the naked eye. At the same time, the VR device should instantaneously stretch your output to fit the viewing area, regardless of its incoming resolution size (Fig. 12).

To conclude, this entire process is actually a derivative process from the visual effects world known as dimensionalisation. In fact, it was once a first, rudimentary step in visual effects attempts to create stereoscopic 3D images by converting monoscopic pictures to stereoscopic. If one did heed the advice above in this entry, this technique is already outdated in the visual effects 2D motion picture world, as many better techniques are now around (which includes proper depth maps, warping, and other tricks that deserve their own exploration separate from this entry). However, if



Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 10 VR panoramic work-in-progress showing the layers in z-depth space and being pulled off the flat image



Virtual Reality Stereo Post-Conversion After Effects Workflow, Fig. 11 VR panoramic work-in-progress showing the black vertical bars in both stereo comps

a pseudo-stereo effect is all that the independent VR filmmaker is after, given the small boutique nature of the filmmaker's VR start-up or one-man show, give this a shot.

The real truth behind this simple workflow for live-action VR content is that there is no "secret sauce." Just lots of tedious, hard work – and a bit of recycling of existing visual effects tricks.

Current Developments and the Future

Today's VR Stereoscopic Tools and Plugins

Speaking of visual effects and trickery, returning back to today's available tools for stereoscopic VR, The Foundry is currently at the forefront in terms of developing tools for today's filmmakers and artists seeking to develop cinematic virtual reality – albeit at a price.

CARA VR is an example of such a development by The Foundry that integrates with their compositing software Nuke, for the purpose of creating, compositing, and polishing captured VR footage, stereo or otherwise. Rather than a lengthy post-conversion process however, CARA VR's toolset simply allows you to stitch and modify monoscopic or stereoscopic VR footage. In other words, although the independent filmmaker would have an easier time modifying VR footage, they would still have less control over the depth intentions in their VR footage.

Moving from Nuke back to After Effects, Mettle's "Skybox" plugin is another example of a development for stereo VR in the postproduction world, where developers and companies are slowly catching up with the increased demand driven by independent filmmakers' interest in exploring both flat and stereoscopic cinematic VR.

Even today's stereoscopic camera rigs are much more accessible, with numerous options, compared to a time, not too long ago, when only GoPro cameras were available with such rigs.

Conclusion

The Nature of Workflows

Ultimately, the nature of workflows is simple – they are always changeable and subject to the demand of the artist and end-user. In the case of the above outlined stereo post-conversion workflow, it shall always serve as an option for the budget-strapped VR filmmaker until newer and better systems and processes have been democratized for the masses with regards to converting flat VR footage to stereo.

Definition

System fidelity is the degree with which real-world experiences are reproduced by an interactive system (McMahan and Herrera 2016).

Introduction

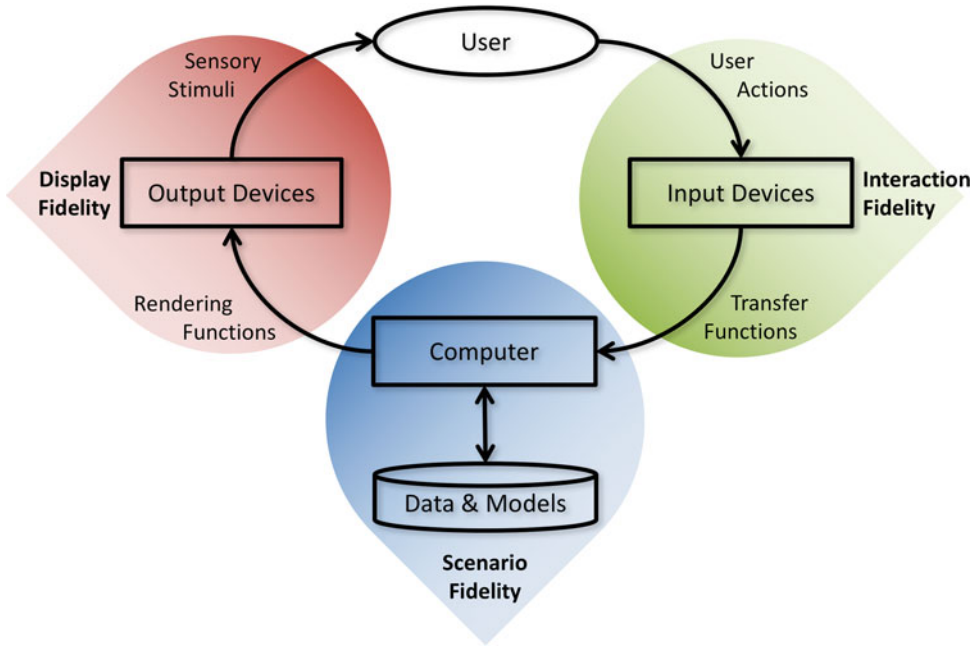
Virtual reality (VR) uses tracking devices, simulations, displays, and other technologies to immerse the user in a synthetic, spatial world seen from a first-person point of view that is under the real-time control of the user (LaViola et al. 2017). Many VR applications have been developed to provide realistic experiences by emulating the real world, such as phobia therapy, military training, and entertainment (Bowman and McMahan 2007). However, the efficacies of these emulated experiences are highly dependent upon the application's implemented system fidelity.

System fidelity is the degree with which real-world experiences are reproduced by an interactive system (McMahan and Herrera 2016). It is a well-structured, hierarchical concept that is defined by the flow of information that occurs when a user interacts with a system. Consider the user-system loop, depicted in Fig. 1. As the user performs actions that manipulate or are directly captured by input devices, transfer functions translate the inputs into meaningful operations. The fidelity of these user actions, input devices, and transfer functions characterizes the system's *interaction fidelity* – the degree with which real-world actions are reproduced in an interactive system (McMahan et al. 2012). How the simulation's data and models determine the outcomes of the meaningful input operations characterize the system's *scenario fidelity* – the degree with which rules, behaviors, and environment properties are reproduced in a simulation, as compared to the real world (Ragan et al. 2015). Finally, the resulting state of the simulation is rendered to the system's output devices, which produce the sensory stimuli that character the system's *display fidelity* – the degree with which real-world sensory stimuli are reproduced by an interactive system (McMahan et al. 2012).

This entry reviews the various qualities and effects of each subcomponent of system fidelity.

Interaction Fidelity

Interaction fidelity describes how realistically users interact with a system compared to the real-world situation that the system is emulating. As depicted in the user-system loop, interaction fidelity depends on the user actions, input devices, and transfer functions that are involved when interacting with a system. The Framework for Interaction Fidelity Analysis (FIFA) defines three major categories of system aspects that influence interaction fidelity (McMahan et al. 2016): biomechanical symmetry, input veracity, and control symmetry.



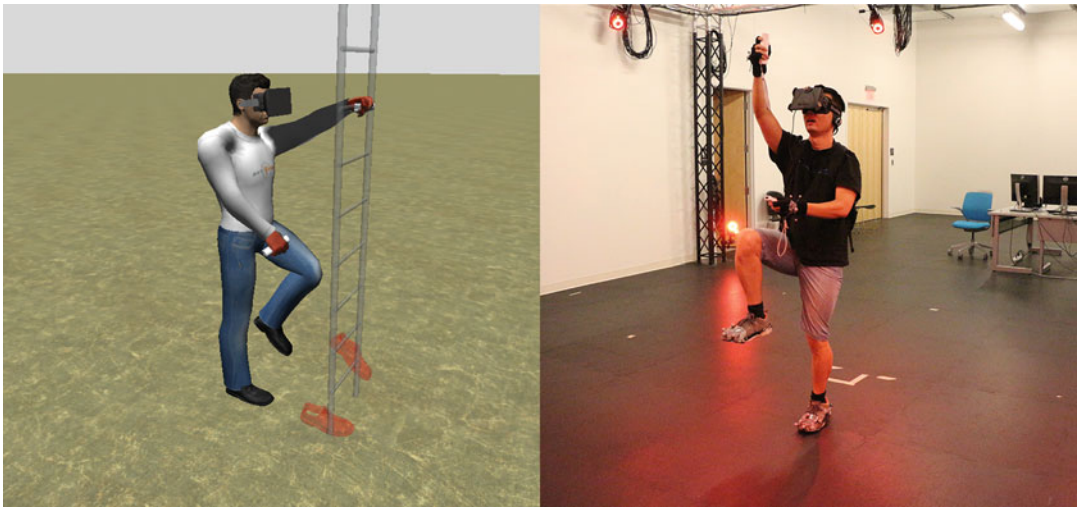
Virtual Reality System Fidelity, Fig. 1 The user-system loop depicts the flow of information in an interactive system. The three subcomponents of system fidelity are also indicated: interaction fidelity (green), scenario fidelity (blue), and display fidelity (red)

Biomechanical Symmetry

Biomechanical symmetry is the degree with which real-world body movements for a task are reproduced during interaction (McMahan et al. 2016). It can be characterized by the *anthropometrics* (i.e., body parts), *kinematics* (i.e., motions), and *kinetics* (i.e., forces) required by an interaction technique. Consider, for example, the March-and-Reach technique (Lai et al. 2015), in which the user must move both hands and both feet to climb a virtual ladder, in comparison to merely grabbing the rungs of a virtual ladder (Takala and Matveinen 2014). The March-and-Reach technique affords more biomechanical symmetry due to requiring more anthropometric symmetry (i.e., the legs) and more kinematic symmetry (i.e., leg motions). See Fig. 2. However, both techniques afford little kinetic symmetry due to missing the external supporting forces provided by the physical ladder rungs in the real world.

Input Veracity

Input veracity is the degree with which the input devices capture and measure the user's actions (McMahan et al. 2016). The input veracity of a system is dependent upon three subcomponents: accuracy, precision, and latency. *Accuracy* refers to how close an input device's reported values are to the "true" values that it is attempting to measure. On the other hand, *precision* refers to a device's ability to reproduce the same results with repeated measures. For example, in a consumer VR system, such as the HTC Vive, the accuracy of the system is indicated by how close the virtual representation of a handheld controller is from the physical controller, while the precision is indicated by the stability or lack of jitter in the virtual representation when the physical controller remains still. Finally, *latency* is the delay between user input and the sensory feedback generated by the system in response to it (McMahan et al. 2016). In consumer VR systems, expected latency ranges between 16.7 ms (60 frames per second) and 11.1 ms (90 fps).



Virtual Reality System Fidelity, Fig. 2 The March-and-Reach technique affords a high degree of biomechanical symmetry to climbing a real-world ladder

Control Symmetry

Control symmetry is the degree with which control in a real-world task is provided by an interaction (McMahan et al. 2016). It depends solely on the *transfer functions* that translate user input into meaningful interactions. For example, a simple virtual hand technique, which directly maps the six degrees of freedom (6DOF) of a handheld tracker to the user's virtual hand, provides a high degree of control symmetry to manipulating real-world objects with one's physical clinched hand, which also affords 6DOF. On the other hand, a ray-casting technique, which manipulates virtual objects with a 2DOF virtual ray at an offset, provides a lower degree of control symmetry.

Effects of Interaction Fidelity

Interaction fidelity has been shown to have significant effects on user performance and user experience. It has been shown to significantly impact performance in manipulation tasks (McMahan et al. 2006) and travel tasks (McMahan et al. 2010). It has also been shown to significantly impact presence (i.e., the sense of "being there"), engagement, perceived usability, and even strategies employed by users (McMahan et al. 2012). However, many of these results indicate that increased interaction fidelity is not necessarily better. In fact, interaction fidelity has been referred to as the "uncanny valley" of VR due to the U-shaped curve produced by mapping levels of interaction fidelity from various studies to their resulting user performances (McMahan et al. 2016). Users' lack of familiarity with mid-fidelity, seminatural interaction techniques is considered the primary reason for this U-shaped curve of the effects of interaction fidelity (McMahan et al. 2016).

Scenario Fidelity

Scenario fidelity describes how realistically the simulation's data and models represent the real world. It depends on the rules, behaviors, and properties of the simulation. These can be categorized as physical coherence, behavioral coherence, and attribute coherence.

Physical Coherence

Physical coherence is essentially how logical and consistent the physics of the simulation are to the real world (Skarbez et al. 2017). Examples of high physical coherence would be a virtual desk supporting a virtual lamp placed on it or a virtual door rotating open when its handle is pulled.

However, there are common examples of poor physical coherence, such as the user walking through a virtual wall or not being able to manipulate a small object within reach.

Several factors affect physical coherence. *Colliders* define how the physics engine (if there is one) will treat a virtual object during collisions. For example, developers will often use box colliders to represent objects to reduce the overall computational requirements of the simulation. However, these box colliders may result in lower physical coherence (e.g., a virtual soda hovering above the opening of a virtual trash can). Once a virtual object is under the influence of the physics engine, there are several physics-based factors that will influence its physical coherence: *mass*, *center of mass*, *gravity*, *velocity*, *drag*, *angular velocity*, *angular drag*, etc. Another factor for physical coherence is the concept of using *constraints* that restrict the movements of objects to certain degrees of freedom, such as restricting virtual travel to the horizontal plane (LaViola et al. 2017).

Behavioral Coherence

Behavioral coherence is how logical and consistent the behaviors of virtual agents (e.g., virtual humans) within the simulation are to the real world (Skarbez et al. 2017). Virtual agents that realistically respond to the user's actions afford high behavioral coherence, while more simplistic agents may fail to realistically respond, hence reducing behavioral coherence.

Behavioral coherence depends on three simulation aspects, like the Model Human Processor (Card et al. 1986): the agent's perceptual model, cognitive model, and motor model. The agent's *perceptual model* defines the information that the agent will make decisions based on. Perceptual models can be quite complex and include aspects such as the simulation state, the spatial properties of objects and agents, the properties of human users, and the spatial properties of the virtual world for path planning (Rickel and Johnson 1999). The agent's *cognitive model* defines how the agent will generate decisions and actions based on the information from its perceptual model. There are four basic types of cognitive models, each with increasing complexity: simple reflex agents, model-based reflex agents, goal-based agents, and utility-based agents (Russell and Norvig 2016). Finally, the agent's *motor model* is responsible for mapping the decisions of the agent into observable events, such as body movements, facial expressions, and speech (Rickel and Johnson 1999) (Fig. 3).

Virtual Reality System Fidelity, Fig. 3 Behavioral coherence depends on the virtual agent's perceptual, cognitive, and motor models in order to realistically interact with the virtual environment and the user

Attribute Coherence

Attribute coherence is how logical and consistent the attributes of virtual objects are to the real world. The factors that primarily affect attribute coherence are the object's mesh representation and material. While a high-polygon *mesh representation* (i.e., the set of polygons that represent the 3D surface of an object) will yield high attribute coherence, it can also negatively impact the simulation's frame rate and, ultimately, the system's display fidelity (Bahirat et al. 2017). Meanwhile, an object's *material* defines the texture maps, colors, and numeric values that will be used to render the object's mesh representation. If an object's material is well crafted, the object may be perceived as having high attribute coherence, despite a possibly low-coherent mesh representation.

Effects of Scenario Fidelity

Like interaction fidelity, scenario fidelity can have significant effects on user performance and the user experience. Physical coherence, particularly constraints, has been shown to improve user performance for various manipulations and travel tasks (LaViola et al. 2017). Behavioral coherence (e.g., the motor control of an agent's gaze) has been shown to significantly impact the perceived plausibility of a simulation (Bergström et al. 2017). Similarly, increased attribute coherence (e.g., mesh representations and materials) has been shown to increase the perceived plausibility of a simulation (Skarbez et al. 2017).

Display Fidelity

Display fidelity describes how realistically the sensory stimuli produced by the system resemble the real world. It depends on the rendering functions, output devices, and the sensory stimuli produced by those devices. There are three major categories of display fidelity, based on the type of sensory stimuli being produced (LaViola et al. 2017): visual fidelity, auditory fidelity, and tactile fidelity.

Visual Fidelity

Visual fidelity is essentially the degree with which real-world visual stimuli are reproduced by an interactive system. For example, a VR head-mounted display (HMD), which provides an immersive stereoscopic view of the virtual environment, affords much greater visual fidelity than a standard-definition, non-3D computer monitor.

Several rendering factors affect visual fidelity. *Culling* parameters determine which objects will be rendered. *Shaders* define how the material properties of objects will be rendered, especially in reaction to the simulation's lights. *Post-processing* effects, such a motion blur, can then be applied to the rendered image. Finally, the computational requirements of these factors ultimately determine the *frame rate* (i.e., how often images are rendered to the graphics buffer).

Several qualities of visual displays also affect visual fidelity (LaViola et al. 2017). A display's *field of view (FOV)* defines the maximum number of degrees of visual angle that can be seen instantaneously. On the other hand, a display's *field of regard (FOR)* defines the total number of degrees of visual angle that surround the user and are accessible. For example, many consumer HMDs provide approximately a 90-degree FOV but a 360-degree FOR. *Stereoscopy* (i.e., the display of slightly different images to each eye) is another common feature of consumer HMDs. *Spatial resolution*, the ratio of display pixels to physical space, often expressed as dots per inch (dpi), is another quality that affects visual fidelity. For example, a handheld 4 K display has much greater spatial resolution than a large 4 K television. Finally, spatial resolution can also affect *refresh rate* (i.e., how often images are displayed from the graphics buffer).

Auditory Fidelity

Auditory fidelity is essentially the degree with which real-world auditory stimuli are reproduced by an interactive system. For example, 3D localized sounds rendered to a set of headphones afford greater auditory fidelity than 2D ambient sounds rendered to a set of speakers, which are prone to cross talk among channels.

Like visual fidelity, auditory fidelity depends on several rendering factors (Taylor et al. 2009). *Sound synthesis* (i.e., the generation of audio signals based on interactions between virtual objects) relies on either physics-based simulations or prerecorded audio samples. *Sound propagation* then determines how the synthesized sounds propagate through the virtual space to the listener's ears based on attenuation, reflections, refractions, and diffractions. These propagated audio signals are then *panned* independently to one or more channels and then *mixed* to produce an auditory image (Gregory 2017). Finally, this auditory image is produced through *acoustic vibrations* with either headphone, which support two channels, or external speakers, which can support multiple channels (LaViola et al. 2017).

Tactile Fidelity

Tactile fidelity is the degree with which real-world sensations of touch are reproduced by an interactive system. The Longbow archery subgame from

		Tactile fidelity	Frequency Amplitude Duration Asynchrony Tactile vibrations Spacing

The Lab, a VR game by Valve, is anecdotally regarded to provide high tactile display fidelity for pulling on the string of an archer's bow by many users.

Several rendering and device factors affect tactile fidelity. The *frequency* and *amplitude* of a tactile signal can have a significant effect on its perceived intensity (Seo and Choi 2010). When multiple tactile signals can be produced, the *durations* and *asynchronies* of the stimuli can create tactile perceptual illusions, such as phantom actuators and apparent tactile motion (Israr and Poupyrev 2011). These tactile signals are then commonly produced through *tactile vibrations* with either linear resonant actuators (LRAs) or eccentric rotating mass (ERM) motors (Tang et al. 2014). The *spacing* of these motors also affects the overall tactile fidelity (Tang et al. 2017).

Effects of Display Fidelity

Display fidelity has also been shown to have significant effects on user performance and experience. Increased visual fidelity has been shown to significantly improve performance in manipulation tasks (Ware and Franck 1996) and travel tasks (McMahan 2011). Visual fidelity also has a positive effect on presence, engagement, and perceived usability (McMahan et al. 2012). High auditory fidelity has been shown to both improve memory recall and increase presence (Dinh et al. 1999). Similarly, high tactile fidelity has been shown to afford the body ownership illusion (i.e., considering a virtual avatar body to be your own), while low tactile fidelity does not (Kokkinara and Slater 2014). In general, unlike interaction fidelity, increasing display fidelity improves user performance and the user experience.

Conclusion

System fidelity is well-structured, hierarchical concept that incorporates interaction fidelity, scenario fidelity, and display fidelity, as depicted by the user-system loop (see Fig. 1). In this entry, each subcomponent has been defined and further decomposed into contributing aspects and factors that influence system fidelity (see Table 1). Additionally, some of the effects of each subcomponent have been briefly discussed, demonstrating that system fidelity can have a significant impact on user performance and the user experience.

Definition

A virtual reality system is a software system that generates the illusion of immersion and presence within a virtual environment. A virtual reality framework is a customizable application that consists of design patterns and components, which assist virtual reality developers with its modularity, reusability, and extensibility. Virtual reality systems and frameworks may be developed using special purpose virtual reality development tools.

Introduction

Virtual Reality (VR) has been gaining a lot of attention in the past few years. Although the first VR Head-mounted Display (HMD) was designed in 1968 by Ivan Sutherland, the broad adoption of the VR technology is realized around 50 years later due to the emergence of affordable VR HMDs, and the maturity of computer graphics. Nowadays, VR simulates interactive virtual environments that immerse users to the extent that they become subjectively involved and experience the illusion of presence. VR research and industry is very active the past few years in the development of innovative methods for VR, VR systems, development tools and VR frameworks.

VR Systems

A VR system is a software system that aims to provide synthetic user experiences that stimulate user senses. Main objective of a VR system is to generate the illusion of immersion and presence within a virtual environment (VE) by providing artificial computer-generated stimuli to the user. In addition, immersed users should have the ability of interacting with the VE in a natural way.

A VE, a key element for every VR system, is a digital model that consists of spatially organized virtual objects. Its utilization assists the simulation and enhances the virtual user experience.

The basic architecture of a typical VR system involves several hardware and software components which cooperate to generate the artificial stimuli. Core of the system is the computational platform that is responsible of running an appropriate game engine, which maintains the VE, keeps track of its state, interprets, and executes user commands. User interaction is accomplished utilizing various input and output devices while the artificial stimuli are presented to the user utilizing one or more output devices.

VR systems are mainly distinguished from other software systems due to the complexity of accomplishing simultaneously system objectives some of which may be conflicting. Such systems are characterized by two defining properties, user immersion and real-time interaction, that help achieve human sensory stimulation. These properties impose a strict set of requirements onto VR systems which are directly deduced by properties of the human sensory system. The requirement of strict real-time performance is set to ensure an acceptable level of realism and presence. Additionally, such software systems need to model the appearance, the functionality, and the physical properties of virtual objects within the VE. As these systems aim to create an immersive illusion for the user, different styles and modalities of interaction techniques in accordance with specific tasks, utilizing input/output devices, should be taken into consideration.

The development of a VR system is a multidisciplinary task involving sensing and tracking technologies, stereoscopic displays, multi-modal interaction and processing, computer graphics and geometric modeling, dynamics and physics enabled simulations. As such, various types of displays, sensors, and computer systems are utilized. Stereoscopic displays aim to deliver the sensory stimulation to the user, sensors detect user actions, while computer systems process user actions and generate the output content. VEs are presented to the user through HMDs that involve sensory display systems, sound speakers, and force feedback devices.

Primary objective of a HMD is to present the VE to the user, hiding the physical scenery. This functionality enhances the full immersion of the user within the VE. HMDs have capabilities of displaying real-time stereoscopic imagery, acquiring head tracking, and providing haptic and force feedback to the user with several degrees of freedom. Also, many HMDs provide other input methods, such as speech recognition, and user data acquisition through data gloves, or data suits. Nowadays, untethered HMDs, having the benefit of being wireless and running on their own computational unit, using ARM processors, are independent of a personal computer (PC). The smartphone technology mVR (Wei et al. 2017) has enabled the production of mobile and low-cost HMDs which use smartphone cases with mounted lenses. Although, this technology seems a promising solution, it may not support

full user immersion since it lacks input control sensors for user interaction.

A data glove is a device that captures the user's hand gestures such as the position of the hand, the orientation of the hand, and the orientation of the finger joints. A pinch glove is a similar device with the data glove with no finger joints orientation measurement. Many other VR input device are also available such as mechanical trackers, electromagnetic trackers, acoustic trackers, optical trackers, inertial trackers, face trackers, haptic displays, cave automatic virtual environment (CAVE), etc.

Successful real-time rendering of complex VE require a powerful special-purpose software engine running on dedicated computational platforms. Nowadays, these technical considerations gradually become less important due technological advances in microprocessors, graphics processing units (GPU), display technologies, motion tracking technology, etc. As such, VE designers focus more on the quality of user experience.

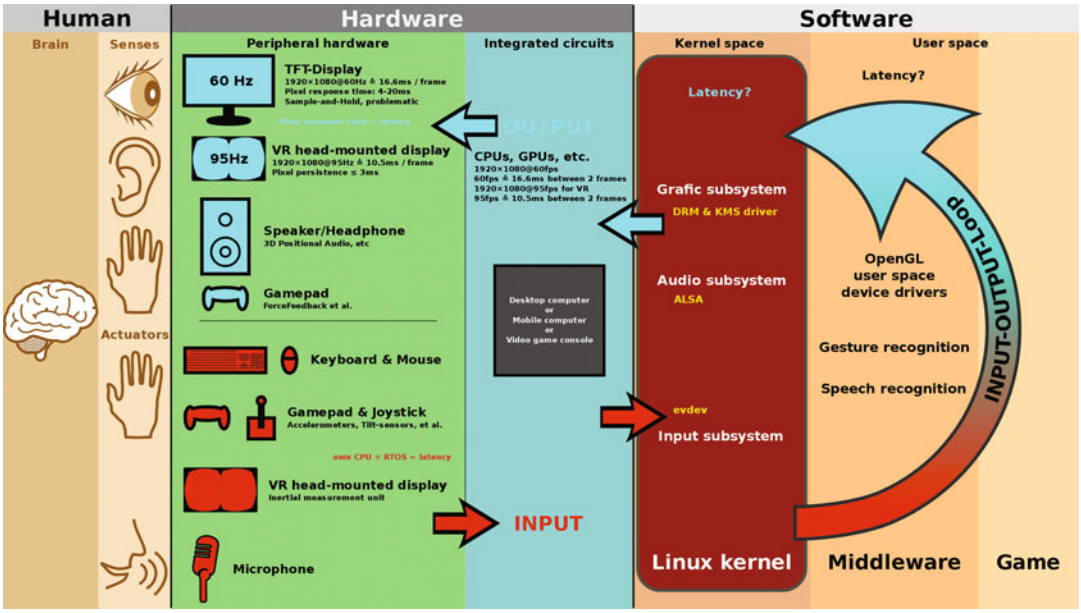
Components of a VR System

The generation of an amination requires the minimal frame rate to be at least 24 frames per second (FPS), while the optimal frame rate may be much higher, 60–100 FPS. This requirement makes the VE engine to be a very important part of the VR system. The VE engine consists of several important components, namely, Scene graph, Graphics Rendering engine (Papagiannakis et al. 2014), Audio engine, the Physics simulation engine, and the user interface (UI) system. The central component of each VR system is the Scene graph, an abstract representation of the VE represented by a data structure containing the properties of each virtual object, such as description, relative position, transformation, lighting, material, and texture. This component contains modules for the stereoscopic display. The Graphics rendering engine is responsible for generating the 2D image that is to be projected on the HMD, by transforming in real-time the 3D scene into a 2D photorealistic image. To accomplish the image generation, the rendering engine considers a mathematical lighting model, with the virtual object geometry and the light reflecting properties of its surface material (Gillies and Spanlang 2010; Jung et al. 2011). The Audio engine generates spatialized audio, simulating the changing properties of 3D sound as it travels from the virtual source to the listener in the VE. In many VR systems, the graphics rendering engine collaborates closely with the Physics simulation engine (Papagiannakis et al. 2018). Physics engines are software modules responsible for simulating the dynamic behavior of virtual objects considering physics laws about forces, masses of objects, friction coefficients, velocities, accelerations, elasticity coefficients, etc. Physics engines contain surface deformation and collision detection modules (Papagiannakis et al. 2018; Xiao et al. 2020). Finally, the UI system is responsible for the interpretation of the acquired, from the various input sensors, user interactions into meaningful gameplay events utilizing the defined game logic.

Figure 1 shows a pictorial view of the entire VR pipeline. The input subsystem receives sensed data from the various input devices which are further processed converted to user interaction commands by the speech or gesture recognition subsystems. Following, depending on the issued user command the OpenGL subsystem generates the new transformation of the virtual environment. Also, the Audio subsystem generates the sound to be played. Last stage of the VR pipeline is the transmission of the image and sound to the output devices.

Depending on the employed computational platform VR systems are categorized as PC-based, mobile, and Distributed VR Systems.

Many VE provide multi-user collaboration that may be supported by distributed VR system architectures. Such systems are mainly distinguished from other distributed software systems due to their strict requirements in terms of presenting a common interactive environment and its state to all users, as well as providing means for mutual communication and collaboration among the users. Furthermore, a fast and reliable data transfer method is also required as these systems produce large amounts of data. In a multi-user VR



Virtual Reality Systems, Tools, and Frameworks, Fig. 1 Important constraints for best immersion are high frame rate and low latency (https://en.wikipedia.org/wiki/Virtual_reality)

system, to maintain the consistency of the VE, all users must be constantly synchronized regarding the state of the VE. Among others, the VE State includes the positions and transformations of virtual objects, their visual appearance in terms of material, lighting, and texture. State synchronization maybe accomplished through various sync strategies: shared repository where the state of the VE is kept in a single location on a dedicated server, frequent state regeneration where each client/peer maintains its own copy of the VE and broadcasts the updated information to every other node in the network, dead reckoning where each client/peer in the network maintains its own copy of the VE, calculates the position of other clients according to their position, speed, and direction and periodically broadcasts basic states to other nodes.

Distributed VR systems (Wei et al. 2017) are mainly designed using similar network architectures as in other distributed software systems, Serverless pear-to-pear (P2P) and Client-Server architectures. In serverless architectures, VR systems are characterized by high availability and extensive bandwidth use. On the other hand, in Client-server architectures, a single dedicated server is responsible for maintaining and transferring the state of the VE to all clients. In this setup, the complexity of the network is simple, but the server is a rather critical point of the architecture. In a multi-server client-server system, the workload is divided across many servers, which raises the number of concurrent users. Also, the communication bottleneck is reduced compared to the single server setup, and there is no single critical point of failure. Such architecture is more complex and introduces much redundancy while synchronizing the state between the servers.

VR Development Tools

Game and VR engines are software tools for the development of interactive VR experiences aimed at generating immersive and photorealistic synthetic environments. VR engineers are required to program in a high-level programming language, have solid modeling knowledge, and graphic design skills. Most popular VR engines may be integrated with customizable VR software development kits (SDK) and application programming interfaces (API).

Unity is a powerful cross-platform game development environment and runtime engine. Unity allows game deployment on mobile platforms, consoles, handheld gaming platforms, desktop computers, TV boxes, and virtual reality systems. Unity's main advantage is the ease of development using an integrated editor environment. It also provides a powerful set of tools for analysis and optimization of the virtual environment for a specific platform. VR engineers may design and manipulate assets and game entities. Scripting may be implemented using JavaScript, C#, or Boo and a shader language for custom GPU shaders. There is also support for network multiplayer games. It provides a built-in physics engine that handles contact dynamics, as well as material simulation. Unity VR systems may be integrated with most common VR hardware.

The *Unreal Engine* provides an extensive set of features and tools. It is a powerful virtual environment development platform and prototyping tool. Scripting may be implemented in C++ and scripting technique called Blueprints Visual Scripting that enables VR engineers to collaborate using the same set of tools. Unreal engine is more complex and sophisticated tool than Unity, but it realizes better performance. It supports all main VR hardware.

CryEngine is another game development platform which offers a rich suit of tools for asset creation. Its powerful runtime engine features high quality real-time graphics targeting into a wide range of platforms. Scripting is implemented with C++. It may support three VR platforms: HTC Vive, Oculus Rift, and Open source virtual reality (OSVR).

WebVR is a recent VR development platform. It contains a JavaScript API that allows VR deployment in most modern browsers. *A-Frame* is an open-source Mozilla project allowing the design of VR experiences using HTML. *A-Frame* project may run on various HMDs, HTC Vive, Oculus Rift, Google Daydream, and Samsung Gear VR. *React 360* is a promising framework that use native react logic using only JavaScript and Node.js.

VR Frameworks

In software engineering, an object-oriented application framework (OOAF) is a customizable set of modules that consist of design patterns, which assist software engineers with modular, reusable, extensible components. VR development involves many intensive subtasks as programming, 3D graphics, animation, and audio engineering. Therefore, it is a complex task. Frameworks tend to reduce the architectural complexity of VR system through reusable system design and common class vocabulary. To this end, a VR framework's objective is to assist VR engineers in developing fast and efficient VR applications. The challenge of a VR framework is to provide abstraction classes of devices, projection system, specialized scene graph, VE interaction system, and support for distributed VR systems, ready for reuse. Therefore, the development process is simplified since generic functions and features are available for reuse at any kind of VR application (Ponder et al. 2003). VR frameworks are scalable and customizable to the developer needs (Papagiannakis et al. 2018). As such, the employment of a VR framework enables the VR engineer to focus on the design of the virtual environment rather than programming the core functionalities of a VR application.

SteamVR framework mainly provides an HMD controller, input mappings, and tracking system. A number of frameworks were developed on top of SteamVR enhance the interactions and object manipulations in the virtual world.

Other frameworks deal with other functionalities like 3D menus and character control systems (Gillies and Spanlang 2010; Jung et al. 2011; Takala 2014; Dam et al. 2015). Many of these frameworks aim to exploit virtual reality as a medical training tool for medical operations (Papagiannakis et al. 2018; Pfeiffer et al. 2018), manufacturing operations (Whitney et al. 2018) or for product marketing presentations (Alcañiz et al. 2019). Although consumer VR systems are now affordable, content creation still requires a significant development effort. Also, some device-agnostic VR frameworks have already been developed that various HMDs without requiring

any special adaptations (Papagiannakis et al. 2018).

Virtual Reality Therapy

Definitions

Virtual Reality Therapy (VRT) refers to the use of Virtual Reality (VR) technologies to conduct therapy by exposing the patients to stimuli in controllable and often interactive virtual environments. These interactive VRT interventions are designed to replicate artificial environments in which the user can experience stimuli tailored to treat a specific ailment. The virtual environments are presented to the user via head-mounted displays, cave automatic virtual environments, or desktop-

screens, while the user input is recorded by sensors, cameras, or traditional keyboard, mouse, and joysticks.

Introduction

By substituting real-world sensory information with digitally generated ones, VRT offers interactive, controllable simulations in which therapeutic interventions can be implemented. One of the first known published studies on VRT assessed the effectiveness of virtual environments in the treatment of agoraphopia: the fear of places that might appear difficult to escape from (North and North 1994). Since this pioneering study, a vast body of research on virtual technologies to treat mental conditions has been conducted. These studies investigate the effectiveness of VRT to treat conditions such as autism (Didehbani et al. 2016), anxiety disorders (Botella et al. 2017), poststroke patients (Lohse et al. 2014), phychoses (Rus-Calafell et al. 2017), and substance use disorders (Hone-Blanchet et al. 2014). The increasing capabilities of VR hardware, combined with its decreasing costs, are making VRT more easily accessible to therapist and mental health professionals. The main opportunity provided by VR technology is the ability to create naturalistic settings in which procedures for treatment of mental disabilities can be implemented. Traditional neuropsychological methods have been criticized due to their limited ecological validity. The critics have questioned the conventional interventions' ability to predict or improve real-world behavior via interventions performed in controlled environments such as the therapist's office (Chaytor et al. 2006). On the contrary, the ecological validity is described as one of the main strengths of VRT due to its ability to offer virtual simulations of reality that require real-world behavior as input from its users (Rizzo and Kim 2005). However, extensive usability testing is required to design natural user interfaces that are easy to use for individuals diagnosed with mental disabilities. The technological advancements in the area of 3D user-interface devices such as the Oculus Rift touch controllers have the potential to provide a user-friendly interaction scheme for future VRT interventions. Another main strength of VRT is the ability to deliver hierarchical treatments across different difficulty levels while supporting repetition in safe and controllable virtual environments. These environments can provide their users with real-time performance feed-back, which is essential to rehabilitation and learning interventions (Evans 2003). Thus, VRT interventions can be tailored to suit different needs and requirements of individuals diagnosed with a mental disorder, while allowing cheap duplication and distribution of the treatments to others with similar needs. Additionally, gamification capabilities of VRT interventions, as well as the possibilities for the sensation of "being there" (Sanchez-Vives and Slater 2005), can further increase the users' motivation for partaking in VRT treatments. In the following sections, a summary of VRT for some of the most studied areas is presented.

VRT for Exposure Therapy

According to the Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association 2013), an anxiety disorder is a mental disorder, characterized by a significant level of anxiety and fear. Treating phobias has been one of the most efficient appliances of VRT (Freeman et al. 2017). VR affords the opportunity to expose the patients to virtual environments that seek to provoke anxiety and then remove that anxiety through repetition in a safe and controllable environment. VR exposure therapy is not a new method to treat phobias, but merely a technology that can assist the therapist to conduct traditional exposure therapy in controlled and ecological environments. More specifically, VRT provides access to situations that are otherwise inaccessible or uncontrollable such as fear of heights or flying in Acrophobia patients (Emmelkamp et al. 2002). A recent systematic review of VR exposure therapy for phobias within the past 5 years (Botella et al. 2017) showed that conditions applying VR to perform exposure therapy are significantly more effective than nonactive control conditions. However, the comparison

between VR-based exposure therapy and active-conditions such as in vivo exposure therapy often illustrated no significant difference. A study conducted by Bouchard et al. was alone in finding results favoring VR exposure therapy when treating individuals diagnosed with social anxiety disorder (Bouchard et al. 2017). In their study, a group of 59 patients diagnosed with Social Anxiety Disorder were randomly assigned to three groups: 17 received VRT, 22 received in vivo exposure therapy, while 20 were placed on a waiting list. The individuals put in the in vivo group received standardized treatments for 14 weekly 60 min sessions. All of the therapists involved in the study had at least one year of practical experience with in vivo exposure therapy. The exposure consisted of role-playing and exposure to social scenarios either inside or outside the therapists' office. These included situations such as asking strangers on a date, wearing two socks of a different color in public, giving an awkward speech to an audience consisting of the therapists' colleagues, etc. The VRT exposure treatment consisted of eight different scenarios such as meeting unfriendly neighbors, having a job interview, or introducing oneself to strangers. Posttreatment effects were measured using Liebowitz Social Anxiety Scale. Improvements were measured on both the VRT and the in vivo group. However, results indicated that exposure in VR was more effective than in vivo. A follow-up study showed that the improvements were maintained after 6 months.

VRT for Autism Spectrum Disorder

Autism Spectrum Disorder (ASD) describes a wide range of pervasive, lifelong neurodevelopmental disorders characterized by severe impairment in social and communicational skills of individuals diagnosed with it (American Psychiatric Association 2013). Social skills training (SST) interventions such as role-playing, social stories (Delano and Snell 2006), and video modeling (Bellini and Akullian 2007) are currently being used to teach people diagnosed with ASD ways to appropriately interact with others. VRT as an SST intervention enables rehearsal of social skills in control environments, allowing the individual to work at his or her own pace. This is particularly useful for the ASD population given their discomfort with unpredictable situations and interaction with other people. Given the VR technology's ability to provide a continuous stream of artificial stimuli that leads to the perception of ecological and nonsynthetic environments, it is possible to assess and practice social scenarios and encounters (Adjorlu et al. 2017; Mitchell et al. 2007). Additionally, multimodal interfaces can provide better learning conditions via cognitive integration and limited cognitive load compared to single modality learning interfaces (Moreno and Mayer 1999). It is argued that daily living skills training that involves spatial and visual cues, which is the case with VRT social skills application, is more preserved in children and adolescents diagnosed with ASD. Technology-based learning interventions have generally been suggested to be useful learning tools for young people with ASD (National Research Council 2001). The primary application of VRT for the autistic population has been to create social scenarios in virtual environments that provide relevant contexts for learning. Didehbani et al. (2016) measured the effects of social skills training in virtual environments on a total of 30 children between the ages of 7 and 16 diagnosed with ASD. These virtual environments consisted of a variety of locations including a school classroom, a canteen, a playground, and a park. Each participant completed ten VRT sessions with a peer and two trained clinicians experienced in working with ASD. The clinicians and the participants all logged into the same virtual environment. The participants logged in with avatars designed to look like themselves. One of the clinicians logged in as a social coach, while the other played different roles in the social scenarios. The VRT intervention required interaction via keyboard, mouse, and microphone while pro-viding feedback via 24-in computer screens and headphones. The scenarios were designed to target social learning objectives in every-day real-world situations often faced by children. These include dealing with a bully, bonding with a

friend, meeting new people, or handling social dilemmas. During each of the 10 VRT sessions, three different scenarios were used, each consisting of ten minutes of interaction within the VR environment followed by five minutes of therapy with the clinician. Pre- and post-treatment measurements were performed using a Developmental NEuroPSY-chological Assessment (NEPSY) toolkit, as well as Social Attribution Task. The results revealed improvements in the participants' measured social skills, shedding light on the potential of VRT as a treatment tool for children diagnosed with ASD.

VRT for Poststroke Patients

A stroke occurs when the blood flow to an area of the brain is cut off, depriving the brain cells of oxygen and thereby killing them (Sardegna 2002). The death of brain cells results in the loss of the abilities controlled by that area of the brain. Around two-thirds of stroke survivors will therefore have some disabilities. These deficits are often motoric functions, requiring a considerable amount of practice to induce functional recovery (Kwakkel 2006). However, research indicates that poststroke patients perform limited repetitions of the required movements in the traditional therapy sessions (Lang et al. 2009). Furthermore, some motivational, logistical, and individual barriers limit the effectiveness of conventional therapy for poststroke treatment (Langhorne et al. 2009). VRT is one of the proposed methods to intrinsically motivate the poststroke patients in performing the required therapy sessions while removing the physically demanding traveling required for face-to-face interaction with the therapist (Lohse et al. 2014). The user interacts with VRT environments designed for poststroke rehabilitation through a variety of mechanisms. These can include sensors or cameras designed to measure the users' physical movement, while appropriate feedback is delivered via head-mounted-displays or screens. A review on VRT intervention for poststroke rehabilitation (Lohse et al. 2014) showed that in general, VRT was a slightly more efficient approach for upper-limb training compared to conventional interventions when measured using the Fugl Meyer Upper Extremity Scale. Subramanian et al. (2013) compared upper-limb in virtual environments to conventional physical environments on 32 participants sustaining a stroke 6–60 months before the study. The baseline of participants' stroke severity was set using the Fugl Meyer Upper Extremity Scale followed by a randomized placement of the participants in the VRT and the conventional therapy group. The task of both the VRT and conventional therapy group was to repetitively point towards six targets place just beyond arm's length without physically touching the target. Each therapy session averaged 45 min in both environments, repeated for 12 days spaced over 4 weeks. The poststudy assessment using the Fugl Meyer Upper Extremity Scale showed improvement in both groups, while the VRT group slightly outperformed the conventional therapy group. According to the authors, the slight improvement of the VRT group might be due to the extrinsic motivation induced by the implemented scoring system as well as the interactivity and novelty of the system.

VRT for Psychosis

Psychosis describes a range of psychotic disorders that involve disturbances in thought, perception, cognition, and social functioning of individuals diagnosed with it (Al-Diwani et al. 2017). The most common form of psychosis is Schizophrenia, a mental disorder that results in failing to understand what is real, often resulting in hallucinations and delusions (American Psychiatric Association 2013). The conventional treatment has been medication and, to a lesser extent, cognitive remediation therapy. Traditional neurocognitive assessment of individuals diagnosed with psychosis mental abilities in a laboratory setting has been criticized for having limited generalizability to real-world contexts (Chaytor

et al. 2006). Studies on VRT interventions for assessing psychotic symptoms, treating psychotic disorders, or enhancing the understanding of them have proven effective (Rus-Calafell et al. 2017). Sorkin et al. (2008) used a VR environment to measure the distortion in reality perception in schizophrenia patients. A total of 43 Schizophrenia patients and 29 healthy controls navigated through a predetermined path in VR environments consisting of a residential neighborhood, a shopping center, and a street market. The VR environments were designed to resemble the real world as close as possible, except some predetermined incoherences. These incoherencies included colors such as a pink road crossing and clouds, sound such as a guitar emitting trumpet sounds, or locations such as a live giraffe located in an interior store. Results indicated that 88% participants diagnosed with Schizophrenia failed to detect the incoherencies, while all of the participants in the control group rightly detected them.

Cognitive Remediation Therapy (CRT) is an intervention designed to improve neurocognitive abilities such as attention, memory, and executive functioning, often performed on individuals diagnosed with psychosis (Wykes and Spaulding 2011). Chan et al. (2010) conducted a study to investigate the effects of VRT as a cognitive remediation therapy tool for older adults with chronic schizophrenia at care-center for people with mental illnesses. A group of 12 participants received VRT-based CRT in 10 sessions. The system consists of a camera that via computer-vision algorithms tracks the users' body movements, while feedback is provided to the user via a big screen. Two VR activities with the purpose of training the participants' attention, memory, and executive functioning were chosen. These consisted of an activity that involved the participant attempting to block the path of balls flying towards him using his body movement and another activity within which the participants avoided getting attacked by sharks in their way by leaning from side to side. The participants' posttreatment performance was measured using the neurobehavioral cognitive status examination (Cognistat) and compared to a control group that received the standard treatment offered at the care center. The overall cognitive functioning performance of participants in the experimental group was significantly better than the control group, showing the potentials for VRT treatment for individuals diagnosed with Psychosis.

VRT for Substance Use Disorders

According to the fifth version of the diagnostic and statistical manual on mental health disorders (American Psychiatric Association 2013), Substance Use Disorder (SUD) refers to the overuse, dependency, and craving for substances that lead to clinically significant impairment or distress. These include substances such as nicotine, alcohol, crack cocaine, and methamphetamine. Treatment of SUD via pharmacotherapies exhibits relatively poor success rates, showcasing the need for more effective interventions (Hone-Blanchet et al. 2014). Studies show that Cue-Exposure Therapy (CET) in combination with pharmacotherapy is necessary for treating SUDs (Perry et al. 2011). Individuals diagnosed with SUD have often established an association between visual cues (objects such as syringes or environments such as bars) to their psychological craving response. CET designed for individuals diagnosed with SUD aims at exposing the patient to the visual cues associated with their cravings. Being exposed to these visual cues without the presence of the actual craving inducing substance will decrease the negative reactivity to the visual cue.

Kuntze et al. (2001) conducted the first study to investigate the effects of VR as a CET tool for individuals diagnosed with SUD. A virtual environment presents the user with a bar scene, with visual cues such as syringes. Via an in-between study, three different groups, each consisting of five individuals with opioid dependence, went through three different treatments: CET via VR, CET via pictures, and CET via books. A variety of craving scales were measured at baseline and

during and after the interventions. All five individuals in the CET via VR group reported unpleasant feeling and urges to use Heroin. Applying VR IN CET treatments exceeds traditional CET designs, which mainly uses substance-related cues detached from its in vivo context (Drummond and Glautier 1994). A range of studies has since confirmed the positive effect of VR to induce craving for substances such as cigarettes and alcohol, indicating VR as an applicable tool to perform CET (Hone-Blanchet et al. 2014). However, there is a lack of studies investigating the long-term effects of VR-based CET.

Conclusion

A majority of studies on VRT, concerning the treatment of anxiety disorders, have found it a promising method of treatment in psychiatry albeit its full potential has not yet been explored. Despite an exponential increase of publications on VRT interventions, the utilization of VR to treat other common mental disorders such as ASD, psychosis, and depression is still in its preliminary stage, yet to be fully implemented in the clinical contexts. In general, research on VRT is often obscure, distinctly piecemeal, and seldom lived up to the standard of what is expected in clinical research today. This could be due to the novelty of the technology as well as restrictive access to individuals diagnosed with specific neuronal disabilities; thus, VRT is an area of research ripe for future work. The director of the Medical Virtual Reality at the University of Southern California, Albert "Skip" Rizzo, argues that VRT has the potential of being a revolutionary tool for psychologist, by merging the control of laboratory settings with the ecological validity of real-world environments (Parsons 2016).

Definition

Virtual reality model allows the user to subjectively be involved and become immersed within a computer-generated environment. As the physical world is hidden, the user realizes the virtual environment as real while the acquired sense of presence enhances the feeling of immersion.

Introduction

Immersive computing has been gaining a lot of attention the last decade, due to advancements and innovations in hardware and software. The first reference to the term of immersive simulation was done in 1968 by Ivan Sutherland when he designed the first Head-Mounted Display (HMD) (Sutherland 1965). Nowadays, immersive computing enables seamless, and fluid user interaction with technology that gradually becomes smarter as it leverages advancements in deep learning. Emerging applications, such as virtual reality (VR), augmented reality (AR), and mixed reality (MR), enable a fundamental change in the way users interact with software systems.

Immersive Computing

Immersive computing is a new term used to describe applications that immerse the user by blurring the boundary between the digital and the physical worlds, providing an immersive experience. The general concept of immersion (Ponder et al. 2003; Jennett et al. 2008) is mostly used in games and VEs as the involvement of the user in the game environment causing lack of sensing the physical world, as well as providing the sense of presence in the virtual environment. Immersion in virtual reality, is an artificially generated perception of being physically present in a nonphysical environment (Slater 2014). The perception is generated by surrounding the VR user with images, sounds or other stimuli. A VR system places the user inside virtual 3D environment through a special computer graphics system. The user uses a HMD that tracks head movements and update accordingly the displayed images. The graphics system computes perspective-projected images derived from the 3D scene individually to each eye. The 3D scene is a mathematical model that describes the spatial location of the virtual objects, and animations of virtual objects within the scene. Users may interact with the virtual environment using data gloves, or handheld control devices. Main objective of VR is to substitute the physical world perceptions with the artificially generated virtual world. When sensory perceptions are effectively replaced, the human brain infers its perceptual model – its consciousness – from sensory virtual data stream.

Emerging immersive computing applications are changing the way humans interact with mobile smart devices. This technology is realized through four immersive technologies: 360° video streaming, VR, AR, and MR. 360° videos, recorded utilizing omni-directional cameras, allow users - viewers to control viewing orientation during playback. VR presents a simulation of a photo-realistic virtual environment experience, hiding the physical world, and giving users the sense of presence within the virtual environment. AR does not hide the physical world but augments it by overlaying virtual objects on top of the physical objects. MR mixes physical and virtual worlds and allows user interaction between physical and virtual objects in real time.

The term immersion is referred to the sensation of being involved within an environment. It may be categorized in two broad types: mental immersion and physical (or sensory) immersion. Mental immersion refers to an emotional state of the user being involved and deeply engaged in the experience. Immediate result is the suspension of disbelief which is the main objective of media creators. On the other hand, physical immersion is a specification requirement of VR systems, that replaces or augments the stimuli to the participant's senses. Not all human senses are being immersed though. Mental immersion is usually referred to as the sense of presence in a virtual environment (Lackey et al. 2016). VR provides the user the illusion of presence within virtual worlds (Slater and Sanchez-Vives 2016).

VR technology is classified in two categories: immersive and non-immersive (Yoo et al. 2017; Gaggioli et al. 2009). In general, VR technology is considered to be immersive in the case that it can replace the user's perception of the physical world with an artificially generated sensory stream.

Non-immersive VR provides users a computer-generated environment without hiding

the physical world. The user keeps control over the physical surroundings: visuals, auditory, and haptics. As such the user is not being immersed in the virtual world. Such VR systems utilize computers or video game consoles, displays, and input devices.

Fully-immersive virtual reality enables users to experience virtual environments, hiding the physical world. Users perceive only virtual surroundings: visuals, auditory, and haptics. The main objective of this VR category is to enable users perceive the synthetic world as the real one (Krokos et al. 2019). As such, users wearing a HMD are completely isolated from the physical surrounding. Additionally, the use of wireless controllers enables users to explore the 3D virtual environments and interact with virtual content. Fully immersive VR technologies have the potential to provide the user with the sense of full engagement within a virtual environment.

This technology utilizes HMDs in combination with other sensory devices to generate realistic stereoscopic images, animation, spatial 3D auditory, and haptics, to simulate the user's presence in a virtual environment. VR positions the participant's body within the virtual environment to affect virtual interaction events. HMDs are the most common immersive VR technology since they occlude the physical world and replaces it with virtually generated images. The embedded sensors in the HMD provide position and orientation data to the computational unit to dynamically adapt the user viewing angle – position.

Cave automatic virtual environment (CAVE) is an advanced and expensive immersive VR technology (Cruz-Neira et al. 1992). CAVE may be located in a cube-like space surrounding the user in which all six cube-faces (walls) serve as display stereoscopic screens. CAVE environments are restricted to be installed in a dedicated space dedicated that does not allow easy mobility. As such, CAVEs are relatively difficult to be broadly spread for education and training purposes. CAVE technology is particularly used in Cultural Heritage education (Ott and Pozzi 2008) within special theaters or museums.

Utilization of VR Toward Full Immersion

Full immersion is closely related and supported by the term of quality of experience (QoE) which is defined in (Brunnström et al. 2013) as the degree of delight or annoyance of an application or service user. In the case of a multimedia immersive experience, QoE is complex and multidimensional and encompasses several influencing system factors (Ebrahimi 2009), namely, content, network, media, and device-related influencing factors. Content factors include video spatial and temporal resolution, and graphical design elements. Media-related factors refer to encoding, resolution, sampling rate, media synchronization, etc. Network-related factors describe the transmission system (e.g., in terms of latency, delay, loss, throughput), while device-related factors specify the capabilities and characteristics of the systems/devices located at the end points of the communication path.

Based on a comparison study (Broeck et al. 2017), VR HMDs provide the most immersive experience against smartphones and tablets at the cost of high cognitive burden. Furthermore, a user's motion sickness is possible due to visual and auditory quality, interactive and ergonomic experiences, that affect the physical comfort of users. The HMD's ergonomics, weight, shape, temperature, is an essential pillar of a true VR immersive experience. The weight of the HMD should be as low as possible since it is a critical factor for head balance and body posture. Also, the temperature inside the HMD is also a key factor for a true immersion.

Tethered VR headsets (e.g., HTC Vive and Oculus Rift) are connected via cables to VR-ready personal computers (PC) or game consoles. Although these devices realize improved QoE, their users experience limited mobility. MoVR technology (Abari et al. 2017) using mmWave communication instead of HDMI cables provides a solution to mobility constraints but the required data rate is very high, 5–7 Gb/s. The emergence of untethered/standalone HMDs (e.g., Samsung Gear VR, Google Daydream) provide an alternative solution for the mobility issue. An untethered HMD user does not experience

mobility constraint as these devices have the ability to render stereoscopic images using local computational resources (ARM processor). Hence, the approach of combining untethered HMDs with MoVR requires the decomposition of the VR pipeline (sensing, rendering, physics, streaming, displaying) to move part of it on the untethered HMD. Also, an alternative approach moves the entire VR pipeline on the untethered HMD making it PC-independent. It is obvious that both setups, especially the second, experience higher temperatures inside the HMD and fast battery drain.

Physics and rendering processes are the key performance bottlenecks in VR systems. In a distributed VR system, part of the decomposed VR pipeline, computation-intensive tasks (physics, rendering, streaming), is offloaded on a content network server and the untethered HMD displays the streamed images and senses the user interactions. Moreover, to reduce bandwidth consumption the content server encodes the images before transmission, while the headset decodes them before projection. As such, the untethered HMD runs non-intensive tasks, avoiding high processor temperatures and battery drain. Also, as VR applications require better visual quality (e.g., 4K or 8K resolution), parallel rendering and streaming methods (Liu et al. 2018) have been proposed to reduce the end-to-end latency. Also, image caching techniques (Sukhmani et al. 2018) aspire to improve the overall QoE. This approach produces encouraging results in local high-speed networks maintaining QoE. On the contrary, it is rather not feasible to realize mobile immersive applications full potential when relying in 4G networking infrastructure, since the amount of streaming data is voluminous, and the requirement for low latency and high bandwidth is strict. Hence, 5G and edge computing will play a substantial role in making immersive computing a reality.

Virtual reality training for daily scrum meetings

Definitions

A daily scrum meeting is a useful, short, and informal communication activity for agile software development teams typically conducted at the same location and time, most likely before lunch. This meeting allows regular exchange of information among software team members starting with reporting the status yesterday activities to today's tasks and ultimately obstacles that they did encounter.

Virtual reality is a technology medium that allows an interface to individuals to interact with sensory rich computer-generated world, which might also include virtual and real individuals where participants could gain virtual experiences on real matters. Social interactions with virtual personas are considered more engaging and fun especially for training in software engineering concepts.

Introduction

Software development is a social endeavor where quality of social interactions among practitioners directly affects the quality and complexity of software development (Yilmaz and O'Connor 2011b). In particular, software development encourages more diverse teams of individuals and highlights the importance of practitioners' soft skills (Yilmaz 2013). These skills usually developed by the experience of practitioners while working on several different teams and interacting software practitioners with various personality traits (Yilmaz and O'Connor 2012). However, it is technically not that easy to encounter these situations if an individual has been working with a single team of professionals for a long period of time.

In this entry, an industrial case study on a virtual reality training environment for human-virtual persona interaction been discussed to reveal ways to train software professionals for daily scrum meetings with 3D virtual characters which have the ability to mimic verbal and

nonverbal behaviors and therefore convey distinctive personality characteristics.

Overview

In the last decade, agile development has changed the controversial development approaches by investigating practical ways for continuous requirements gathering and feedback with self-organized and self-directed teams and ultimately seeking mechanisms for fostering sustainable software development. These socio-economic mechanisms promote a sequence of refinement to achieve desired outcomes (Yilmaz et al. 2010). However, agile development activities require more social interaction among practitioners, and therefore, social aspects of software development emerged as an important asset for improving the software development process (Yilmaz and O'Connor 2011a).

Daily Scrum Meetings

Scrum is a simple and flexible software development framework and ultimately an enabler based on teamwork with an iterative progress (i.e., a sprint) to deal with volatile requirements (Schwaber 2004). The process essentially starts with a planning meeting, which continues with daily scrum sessions and it ends with a retrospective meeting. These meetings enable software teams to quickly identify and solve the issues as they arise. In particular, daily scrum meetings, which hold every day of a sprint, provide continuous feedback on project status and an opportunity to fix the problems as they arise. In addition, they are helpful for measuring individual productivity on daily basis. To sum up, daily scrum meetings guide software teams for performance visibility, project control and predictability, and ultimately mitigating several risks they might have faced (Schwaber and Beedle 2002). In addition, these meetings are not only for exchanging information but also raising consciousness among software team members who should make continuous planning through a sprint.

A daily scrum meeting requires a well-functioning social interaction pattern; otherwise, it may have unsuccessful results. In addition, it helps to reveal communication problems in software development teams. Although it is not a deep problem-solving meeting, such a face-to-face gathering among the team members requires effective communication and social interaction skills (Schiel 2011). Daily scrum meetings are more likely to be successful when team members known each other's personality characteristics. Consequently, an individual might likely to predict his or her teammate's reaction when a conflict arises. A software team member should share the understanding of team goals, coordinate their work efforts, share their problems and suggestions for improvement, and lastly, they should have to produce a sense of relatedness (O'Connor and Yilmaz 2015).

However, many practitioners reported that they have worked with a limited amount of software professionals and do not know how to respond individuals when engaging a conflict with unknown personality characteristics. To bridge this gap and orient new scrum team members, we propose a virtual reality-based training environment, which is (i) beneficial for onboarding new personnel and (ii) helpful to train individuals who might like to experience a conflict with a virtual character that was designed to have a divergent personality characteristic.

Virtual Reality

Virtual reality (VR) is a technology of illusion (i.e., computer-generated world) encompasses computer vision, digital image processing techniques, and display tools, which enable participants to interact with a digitally simulated environment that have an ability to fool the human senses as an artificial reality (Burdea and Coiffet 2017). VR aims to convince an individual for being in another realm (i.e., hypothetical environment) by receiving and producing data using a computer system.

To design a fully functional training system, a critical feature for a VR system needs to be equipped with 3D interactive virtual characters which may have mimic a set of gestures based

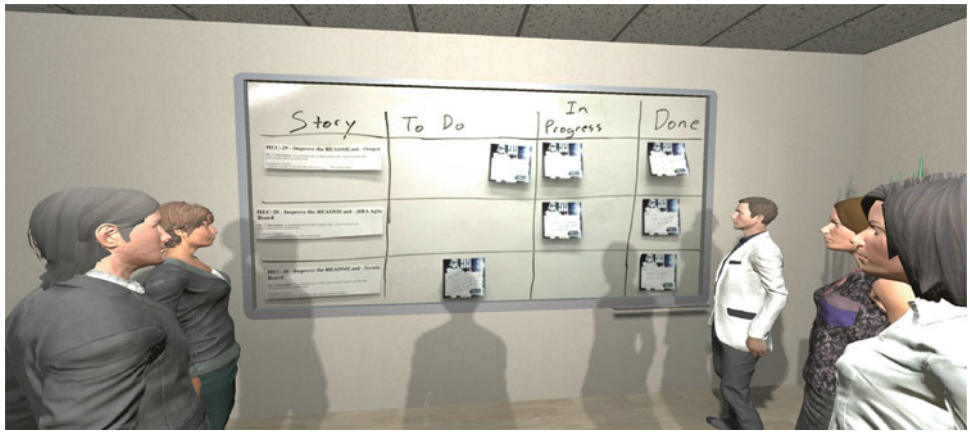
on their embedded personality characteristics. To improve the expressiveness of daily virtual stand-up meetings, we envision that Five Factor (a.k.a. Big Five or ocean) model of personality traits can be utilized for designing virtual personas to improve their social capabilities and make them useful in agile team training activities (Widiger 2017). Five-factor model considers the personality traits of a virtual character in five basic dimensions (Matthews et al. 2003): (i) openness to experience represents persons who are insightful with skills of imagination, (ii) extroversion represents talkative personas with energetic and assertive characteristics, (iii) agreeableness is a trait that shows cooperative behavior with compassion, (iv) conscientiousness is an organized responsible and consistent personality characteristic that shows a tendency to do any task well in a planned way, and finally, (v) neuroticism is a personality trait which is inclined to have long term negative emotions (e.g. anger, anxiety) while being tense and moody.

Personality in virtual characters are designed in terms of their verbal behaviors such as language usage skills (Mairesse and Walker 2010), nonverbal behaviors (McRorie et al. 2012) such as body language or gestures, and lastly facial expressions (Egges et al. 2004). Lui et al. (2016) suggested that extroversion trait in social virtual characters can be portrayed by higher speech velocity and gesture with wider arms than introvert personas. In particular, personality of a virtual agent can be characterized by a set of internally consistent verbal and nonverbal behaviors (Cerekovic et al. 2014). These agents can be formed to simulate different personalities (i.e., individuals with different verbal and non-verbal behaviors) of software professionals and beneficial for creating a variation of virtual daily scrum meetings.

Industrial Case Study: Applying VR to Daily Scrum Meetings

To enhance the virtual reality-based daily scrum meeting training environment, we initially designed five different personas with which participant can join collaboratively to a set of daily scrum meetings. The five personalities of the virtual software practitioners were based on the Ten-Item Personality Inventory (TIPI) scale (Gosling et al. 2003). Unlike human being, our synthetic humans were having more dominant characteristics. For example, virtual character A was designed as an extrovert who prefer to interact with others using verbal and nonverbal behaviors while Agent B was an argumentative virtual character who might avoid from small talk. The personality traits that utilized were as follows: extroverted, conventional, excited, argumentative, self-disciplined, emotionally unstable, and reserved.

Consequently, initial scenarios were created using recorded and transcribed from a set of real-world daily scrum meetings experienced by a small- to medium-sized software enterprise. The agents were hard-coded with predefined gestures and mimics to create a unique training experience to participants. The VR-based training environment aimed to introduce software practitioners seven well-known mistakes might happen in daily scrum meetings. First scenario was about a virtual character who started to take notes while scrum master initiated the meeting. Among active six virtual characters, two of them began to get annoyed from this situation which ultimately reflected to their nonverbal behavior. Here, participant should be able to recognize what was going on and advised to take notes about the issue. Second scenario was about micromanagement issue in a daily stand-up meeting, which was performed by a virtual personality. The virtual scrum master character started to solve a specific problem that was caused by another persona. While meeting was in progress, two other team members started to perform some gestures in response to that situation. In light of these remarks, the participant should be able to spot the problem and later asked to document the issue. The daily stand-up meeting aims to hold the team together by aligning team member's progress with a sprint goal. In the third scenario, virtual team members articulated some sense of disorientation. Initially, a virtual character started to play with their mobile phone during discussions. Participant could report impediments and



Virtual Reality-Based Daily Scrum Meetings, Fig. 1 A daily scrum meeting environment in virtual reality

ways of collaboration for fixing problems. Consequently, other virtual agents started to act in a noncollaborative manner while the other two were annoyed from this situation. Participant should be able to identify this problem and might suggest a solution for reorientation.

Figure 1 illustrates the virtual reality-based training environment where participant is situated in different roles depending on selected scenario. Participant can see all verbal and nonverbal behaviors of virtual characters, which are now in embedded code but planned to be arranged using a simple XML-based markup language.

Agile software development requires quick information exchange; however, the daily stand-up meeting sometimes considered as a planning activity where team leader presents a planned feature. The third training session includes a typical scenario initiated with a discussion regarding to a new feature. Accordingly, scrum master started such a conversation and a virtual character with relatively higher conscientiousness trait might likely to annoy from the situation and probably shows some gesture sequences. Participant should realize the problem and report it back with the user interface. Fifthly, this scenario was expanded to include a detailed technical discussion that should not be conducted during a daily stand-up meeting. All virtual characters partially might annoy from the discussion and highly likely to show their irritation by a set of nonverbal behaviors. An agile practitioner should be able to spot such an issue and report it to a team lead when necessary. In the sixth scenario, participant played the role of scrum master in which team members gathered up in their work location instead of holding the meeting near a scrum board. Consequently, virtual characters started talking to each other by showing some gestures. The goal of participant was to direct them to the right meeting place (i.e., in front of scrum board). Finally, a participant entered the scenario where conventional meeting context was affected by some extra discussions introduced by virtual characters. Participant should have to interact with virtual characters and observe unwanted behaviors. In addition, the main goal of the participant was to keep the values of information, concentration, and entertainment of the virtual daily scrum meeting in balance. In particular, individual should steer the conversations to tasks that they have done yesterday and the things they are working for today. Daily stand-up meetings are usually conducted before lunch; therefore, there would be a space to talk about today's tasks that are in progress. In this scenario, participant was called for an early meeting and further exposed to conversations related to constraints, risks, and obstacles. Participant should have to recognize the issue and report this when asked.

During the study, these seven scenarios were arranged for participants in the form of a set of

VR-based daily stand-up meetings. To investigate scenarios simulated in the VR environment, six software practitioners played all seven scenarios using a Oculus Rift Headset with a pair of Oculus Touch controllers. They were asked to spot a daily scrum meeting issue based on their hands-on experience. The scenario based issues that participants found were shown in Table 1.

Overall, these results indicate that all issues can be visible which were found either one of the participants. Participant one cannot find the daily scrum meeting issue for scenario 2, 3, and 6. Participant two scored six out of seven which is the highest score among all participants while participant three was the one with the lowest found value (i.e., two). Participant four found five issues, participant five and six could be able to report four issues. Not surprisingly, perhaps, participant three was a novice software engineering with less than 1 year of development experience, and participant 2 was a scrum master. Consequently, these preliminary results further highlight the potential benefits of a VR-based software development training.

Limitations

We have initially observed that VR has significantly helped to improve the learning experience for daily scrum meetings in an agile development team. Since the study was also limited to hardware (i.e., a single Oculus Rift was used), it was not possible to conduct concurrent assessments. In addition, it was observed that first time virtual reality users have some stress while experimenting virtual daily scrum meetings. A participant was a bit nervous to experience VR technology and concurrently responding to virtual characters with timely and appropriate responses. Therefore, an assistant observer was used for guidance. After passing the orientation phase, it seems all participants were somehow immersed. To create more realistic daily scrum meetings, a participant suggested that 3D environment should be more detailed with additional background office noises. In addition, another participant suggested that scrum board should be visualized with realistic data and all scenarios should belong to a single project, which would make it more easier to follow. However, these limitations may be improved in further studies.

Conclusion

This entry discussed a virtual reality environment to train software practitioners on daily scrum meetings. The goal was to create a virtual environment with virtual characters to enhance the learning experience of software professionals. Although research has been conducted to transform text-based learning to an interactive form, virtual reality offers an engaging and interactive experience especially by integrating virtual characters that act like human participants. The virtualization of information to use in training is an emerging field in virtual reality applications. Virtual characters with human like gestures and behaviors make a training system interactive and ultimately more engaging for participants. A virtual ecosystem may assist individuals to improve their learning efforts. Based on Scrum

rules that an agile team member should follow, seven different situations were simulated by virtual characters in a 3D virtual reality environment. Although the current study was based on a small sample of participants, the findings suggested that VR-based simulations could be helpful for training software practitioners. In other words, this study strengthens the idea that a scenario-based virtual reality training benefits software practitioners. There is a potential to gain virtual experience on various software development activities. Further research could also be conducted to determine the effectiveness of virtual characters in education and training in software engineering.

Although virtual reality is an emerging medium within a wide range of potential applications, it still has some reachability issues. However, there are massive amounts of investments in VR ecosystems by technology giants such as Google, Apple, HTC, etc. Therefore, this problem will be overcome with these massive investments. Finally, training in a virtual reality environment with virtual characters can be considered as an enjoyable experience particularly for technology enthusiast, like majority of the software practitioners.

Virtual World, a Definition Incorporating Distributed Computing and Instances

Kim J. L. Nevelsteen

Synonyms

Massively multiplayer online role-playing game (MMORPG); Multiuser virtual environment (MUVE); Online world

"Virtual World" Definition

A simulated environment where MANY (one or more) agents can virtually interact with each other, act and react to things, phenomena and the environment; agents can be ZERO (exactly zero) or MANY human(s), each represented by MANY (a virtual self is not required to be unique herein) entities called a "virtual self" (an avatar), or MANY software agents; all action/reaction/interaction must happen in a real-time shared spatiotemporal nonpausable virtual environment; the environment may consist of many data spaces, but the collection of data spaces should constitute a shared data space, ONE (one and only one) persistent shard.

Introduction

There is no generally accepted definition for a virtual world, with Schroeder (2008) highlighting the need for a definition. There is controversy on the meaning of the term "virtual world" in various communities and research (Combs et al. 2004; Brennan 2009). Advances in systems architecture techniques such as host migration between instances, and distributed computing, bring in to question whether those architectures can actually support a virtual world. When a virtual world is not well defined and without a concrete definition, designing an architecture specifically for a virtual world is problematic, for example, tactics often used in existing publications are refraining from providing a reference to the virtual environment used, naming properties that constitute the virtual environment relative to their publication, or only referring to examples of existing implementations. Current definitions simply do not correlate to contemporary technologies, allowing for the classification of technologies such as the online productivity tool, Google (2007) Docs (GDocs); the video game, Leagues of Legends (LoL) (Riot Games 2009); the many shards of the virtual world, World of Warcraft (WoW) (Blizzard Entertainment 2004); or Facebook (2004). It does not buy us anything to refer to

everything as a virtual world, even though it might be possible.

To verify the definition, it is compared with related work. The properties found in Bell (2008) and Girvan (2013) provided a starting point for finding the properties contained herein. Results of this article include a detailed definition for a "virtual world," with detailed definitions of all underlying properties used. The resulting definition is tied to the accepted definition of a net-VE, by Singhal and Zyda (1999). And the concept of pseudo-persistence, by Söderlund (2009), has been used to categorize those technologies which only mimic persistence.

Definition Comparisons

Singhal and Zyda (1999, p. 3) state that a net-VE can be distinguished by five common features: a shared senses of space, a shared sense of presence, a shared sense of time, a way to communicate, and a way to share. A virtual world can be classified as a net-VE, where the multiuser restriction is relaxed to allow local play and simulations with no humans, and the environment is required to be persistent. A "shared sense of space" and a "shared sense of time" can be assumed to be equal to shared real-time spatiotemporal environment in definition herein. One disturbing sentence from Singhal and Zyda is that the place in a "shared sense of space" "may be real or fictional." It is assumed that this statement is mentioned to include the physical aspect of a video conference, but not meant to include pervasive systems (Nevelsteen 2015). If the latter is the case, there is not enough clarification provided to handle pervasiveness (see Mixed Reality (Milgram and Colquhoun 1999)), for example, if a virtual persona is projected into the physical world, is it still a net-VE? Singhal and Zyda's a "shared sense of time" implies real-time interaction, but in definition herein it is made explicit. A "shared sense of presence" implies support for avatars that can be "synthetic entities"; again this aspect is made explicit in definition herein through requiring software agents. The need for an avatar, mentioned in the "shared sense of presence," arises out of the fact that a net-VE is defined as a multiuser environment. It is not clear if the avatar requirement has a uniqueness constraint. In definition herein, a "way to communicate" and a "way to share" are considered part of action and interaction, with the different types in-game communication left as a distinguishing characteristic of different virtual worlds. Using both definitions, GDocs classifies as a net-VE, but not as a virtual world.

R. A. Bartle offered an updated definition in 2010 with respect to his previous publication (Bartle 2003), including the persistence criterion, stating a virtual world to be "an automated, shared, persistent environment with and through which people can interact in real time by means of a virtual self." The automated property specifies a set of rules by which players can change the world, but does not mention how the world can develop internally (previously a part of the persistence property). The definition refers to a shared environment, where "more than one player can be in the exact same virtual world at once," but usage of the term "virtual world" in the description leads to a recursion; it can be assumed to mean a shared spatiotemporal environment, but if the description is to serve as a definition this is problematic. The definition mentions interaction within the virtual world for people, but does not mention virtual interaction in the world, for example, software agents. R. A. Bartle (2010) altered the persistence criterion to state: "if you stop playing [and] then come back later, the virtual world will have continued to exist in your absence." The statement guarantees world persistence and can be assumed to include the nonpausable criterion, by Bell and Robbins-Bell, but fails to account for the difference between persistence in a single-player video game and a virtual world. Also, pseudo-persistent worlds such as LoL are not accounted for. R. A. Bartle's definition of a "virtual self" has been adopted in definition herein, but the uniqueness criterion have been dropped. Since time and space are not elaborated on the definition in R. A. Bartle, it can be said to describe a persistent communication technology, that is, including virtual worlds, but also including technologies such as GDocs.

Through literature review, Bell and Robbins-Bell (2008) offer the definition of "a synchronous, persistent network of people, represented as avatars, facilitated by networked computers." The term " synchronous" in the definition refers to synchronous communication. Although this seems to be similar to the real-time property, synchronous is only applied to communication in their definition. The real-time property specified herein requires real-time interaction, which includes communication. The term "synchronous" is also ambiguous when referring to communication, for example, Bell and Robbins-Bell (2008) states "a synchronous environment does not require the sender of a message to wait for the other party," whereas a synchronous communication protocol is one where the sender **does** wait for a response. Bell and Robbins-Bell offer a citation for synchronous communication, but the underlying reference refers to sending and receiving messages while users logged on simultaneously, which is irrelevant in determining real-time interaction when both users are logged on. Synchronous communication is said to imply the concept of continuous common time (similar shared temporality in definition herein) and bring about a sense of presence. Bell and Robbins-Bell use R. Bartle (2003)'s criterion for persistence, but add that "a virtual world cannot be paused," differentiating them from video games. This criterion has been adopted in definition herein. A "persistent network of people" is mentioned in their definition, but persistence and a network of people is handled separately in their text; a persistent network of people is not the same as a world that stays in existence, unless worldliness is only defined in function of people. Linked to synchronous communication, Bell and Robbins-Bell refer to social grouping behavior and a primitive form of ecosystem, leaving a "network of people" to mean the social construct. In the definition herein, single-user environments are allowed, making no requirement of social networking, although social networking might be probable in a multiuser virtual world. Bell and Robbins-Bell define an avatar and state that it should have agency (e.g., "a Facebook profile does not have agency beyond its creator"), functioning "like user-controlled puppets. Users command the actions of the avatar, but it is the avatar itself which performs the action." This view would seem to deny an immersive "ego-referenced" (Milgram and Colquhoun 1999) perspective that virtual reality strives for; the reader is referred to Waggoner (2009) for a discussion on this matter. The definition of a virtual self, by R. A. Bartle (2010), was adopted in definition herein. The criterion "facilitated by networked computers" serves to ensure an environment simulated by computers is being referred to and that those computers are networked. The definition herein does not require multiple users or networking.

Girvan (2013) states a virtual world to be: "a persistent, simulated and immersive environment, facilitated by networked computers, providing multiple users with avatars and communication tools with which to act and interact in-world and in real-time." The definition is compiled through literature review, but unfortunately the sampling is heavily biased towards Second Life (Spence 2008) with 47 out of 68 surveyed articles referring to Second Life. The definition herein agrees with many of the properties in this definition, but "immersive" is identified as a qualitative property that is subjective. As with the case of a net-VE above, the definition herein does not require multiple users or networking. The definition herein is similar to the one from Girvan, in the sense that action and interaction are separated. Girvan does not define shared time or space, which is especially problematic when dealing with video games, instances, or ad hoc networking.

Overview

Semantics

It is important to clear up the semantics surrounding the term "virtual world"; perhaps one reason for the lack of definition is a language problem. The word "virtual" can be used to mean "being such in power, force, or effect, though not actually or expressly such" (Dictionary.com 2015, "virtual"). This leads to an interpretation of, for example, a "virtual world of electronics," that is, there

is almost an entire world of electronics or an imaginary world consisting entirely of only electronics. The meaning of "virtual" related to computers can be defined as "temporarily simulated or extended by computer software" (Dictionary.com 2015, "virtual"), leading to usages such as a computer-generated visualization of the digital world of electronics or a simulation of a world. The word "temporarily" in the definition can be justified by the fact that it is nearly impossible to create a truly persistent world. This article shall concentrate on the lattermost meaning of a virtual world, being a world simulated by computers, ruling out the imaginary. In popular discourse, when dealing with mixed reality, it is sometimes helpful to regard the system as "a virtual world overlaid on the physical world" (Lankoski et al. 2004), which can be understood as the world of the virtual, that is, those components that are virtual, in contrast to physical. And lastly, "the word 'virtual' has come to mean anything online (as in 'virtual money')" (Schroeder 2008), so the property of being online is added to the study. By definition, the term "online" means "with or through a computer, especially over a network" (Dictionary.com 2015, "online"), implying virtual and networking.

According to Qvortrup (2001, p. 26), the term "world" refers to "the all-encompassing context for the totality of human activities and experiences." Creating such a world might prove impossible. By creating a virtual world, an allegory of the physical world is modeled or simulated. Oddly enough, "world" is not equal to a planetary world, for example, a virtual world can consist of one or more planetary worlds as in EVE Online (CCP Games 2003). A difficulty in obtaining a definition lies in quantifying the "world" of a potential virtual world, that is, determining if the world qualifies as "worldly" enough. Herein, it is assumed that a world is an environment that consists of people, places, and things, sharing time and space.

Virtual (Simulated) Environment (VE)

For the purposes of this article, a VE is considered to be minimally one, that is, "wholly synthetic" (Benford et al. 1998), simulated by a computing device, and supports the least spatial property of containment (Benford et al. 1998). Milgram and Colquhoun (1999) clarify that a VE is one "which must necessarily be completely modeled in order to be rendered"; contrary to the real (physical) environment over which "the computer does not possess, or does not attribute meaning to, any information about the content."

It should be noted that there are several abstractions of simulation possible within a computing device, for example (in general), the micro instructions of the CPU simulate instructions of the CPU or architecture, which in turn simulate assembly or higher level languages, which in turn simulate the operating system of a computer, and which in turn can simulate the software engine simulating a VE. If a technology can provide for one or more (MANY) "data spaces" (Nevelsteen 2015), then the loaded state in MANY data spaces can possibly constitute a VE. It is possible to have one or more environments, nested in other environments (e.g., multiple software running on the OS); a virtual world is then a specialization of one or more VEs. This logic is counter to the initial choice of words by R. Bartle (2003), who found "world" more encompassing, because he found it "not so easy to see how you could have several worlds within an environment" (Combs et al. 2004, #9). Of course, when Bartle was creating MUD (Bartle 2003), the science fiction universe of EVE Online did not exist, that is, many planetary worlds in a science fiction space odyssey.

In the updated definition by R. A. Bartle (2010), he specifies that a virtual world should be "automated," implementing a "set of rules (its physics)". The property of a virtual world being automated is captured here by referring to a simulation, where the simulated environment has its rules or physics.

Properties of the Definition

In each section below, individual properties found in the definition of a virtual world are detailed.

Simulated (ST) and Virtual Temporality (VT) Similar to simulation, there are several layers of abstractions present when examining temporality in computers, for example, the internal hardware might run at a particular frequency (a number of cycles per second, Hertz); computer programs are perhaps triggered according to an internal clock; and the operating system might have another abstraction of time, that is, there can be an arbitrary number of abstractions of time.

If the internal clock frequency is referred to as hardware temporality, then next level up from this can be referred to as ST; a computerized clock (usually at an accuracy of milli- or nanoseconds) that emulates "real-world" (Zagal and Mateas 2007) time. Software in the computer, making use of ST, uses the current time of the clock (i.e., objective time (Nevelsteen 2014), e.g., 5 am). The computerized clock can be altered independent of real-world time, since it is simulated. Since instrumenting real-world time is often wrought with instrumentation error, the computerized clock is usually not exactly equal to real-world time. And so, real-world events are recorded according to ST as they enter the system.

A software package running in a computer will run according to ST, but can provide another abstraction of time, which can be used by its loaded state, that is, the abstracted time for the loaded state can be altered independently of the computerized clock. The abstraction of time in the loaded state can be referred to as VT, that is, a simulation of temporality in the loaded state relative to the ST of the computer system. Entities in the loaded state making use of VT use either the elapsed time (i.e., subjective time (Nevelsteen 2014), e.g., 3 s) relative to the ST or the current virtual time (i.e., objective time). It is precisely VT that allows the state to be persisted to storage and reloaded, or time in the environment to be paused.

Shared Temporality (1T) Interacting agents, HA or SA, can cumulatively share abstractions of time (their timelines overlap) together simultaneously: real-world, hardware, ST, or VT. 1T means agents are able to share simultaneously real-world and exactly one (ONE) VT, with other agents or entities they are acting upon.

Shared Temporality requires: VT.

Real-time (Rt) When describing a virtual world as Rt (not turn-based and not tick-based games, where players must wait for other players to complete their actions before a new round can begin (Zagal and Mateas 2007)), it implies a world where:

- Players can perform actions simultaneously (Wikipedia 2015b) (the synchronous communication mentioned by Bell and Robbins-Bell (2008) is a subset of this interaction).
- The game world is available and action immediacy is part of the game design (Zagal and Mateas 2007).

It should be noted that Rt is not the same thing as a game with real-time computing constraints; a Rt game is contrary to turn-based, whereas a game with real-time computing constraints must complete computations before certain time deadlines. Although latency reduces the feeling of a game being Rt (Zagal and Mateas 2007), massive amounts of latency do not suddenly keep an environment from being a virtual world, just a very slow one, for example, massive space battles in EVE Online have been known to reduce graphics to a slideshow of images (Drain 2008). Performance is an issue for virtual worlds, but missing deadlines do not constitute system failure as in real-time computing.

Virtual Spatiality Aarseth (2001) states that "computer games are allegories of [physical] space." This is similar to the feature, determined by Singhal and Zyda (1999), that net-VEs provide a "sense of space" for all participants. And, similar to what Raph Koster refers to as a "spatially based depiction" of a VE (Combs et al. 2004, #33), Benford et al. (1998) have classified a scale of spatiality, with "containment only" on one end of the spectrum and a "shared spatial frame" (e.g., a Cartesian coordinate system) on the other, having identified "fundamental physical spatial properties such as containment, topology, distance,

orientation, and movement." Movement is an important factor in VT (Benford et al. 1998), for example, in MUD you move through seemingly continuous space (Qvortrup 2001, p. 28) but in discrete steps. In a graphical world, the equivalent would be moving from pixel to pixel in the frame of reference.

Shared Spatiality (1S) Singhal and Zyda (1999) describe "a shared sense of space" such that: "all participants have the illusion of being located in the same place, such as in the same room, building, or terrain. That shared place represents a common location within which actions and interactions can take place. The place may be real or fictional." Note that the description does not exclude single-player games (i.e., technologies with just ONE human agent and SA), even though the net-VE, by Singhal and Zyda (1999), is described as a multiple user systems. The description is problematic for two reasons: First, telepresence, where users see into each other's physical space, is included in the set of net-VEs. If the definition herein is for a "pure" virtual world, then "the place may be real" should be excluded. Second, "the same place, such as in the same room, building, or terrain," is too restrictive. If "the same place" can be understood as the same virtual world, with (possibly multiple) different terrain and physics, then this part of the description is OK.

Benford et al. (1998) state that "Logically, the shared space in which a cooperative activity occurs can be defined to be those aspects of the system which are independent of any single participant or group of participants and which are agreed on by the participants." This description is problematic, because it is dependent on the architecture serving the virtual world; if 1S is to be "independent of any single participant or group of participants," then having a single participant or group of participants hosting the virtual world is not allowed. In definition herein, P handles this aspect.

Shared Spatiality requires: VS and 1Sh.

One Shard (1Sh) Closely related to architecture, technologies can be examined to see if they are contained within exactly one (ONE) shared data space, ONE shard ("an Ultima Online fiction to explain how come there are multiple copies of a supposedly single world" (Bartle 2003)), rather than MANY. Two ways, to partition a VS to allow for scalability, are regions and shards (Liu et al. 2012; Dionisio et al. 2013). Using regions, the VS is divided into static or dynamic areas, with each area handled by a different group of servers; players can still move throughout the entire VS. With shards, players are divided up into groups and assigned to a unique copy (a shard) of VS, with each shard handled by a different group of servers; players are prohibited from moving between shards. Shards are copies of the same VS that do not synchronize with each other. Note that a shard can be divided up into regions. To examine for the presence of 1Sh, technologies must be examined to see if players share a common data space; with regions players still share VS, with MANY shards, they do not.

Things or Phenomena Simulating things or phenomena using an object-oriented paradigm means implementing in software a basic game object ("The collection of object types that make up a game is called the *game object model*. The game object model provides a real-time simulation of a heterogeneous collection of objects in the virtual game world" (Gregory 2009, original italics).) with the most trivial needed properties (e.g., position, orientation, description or visual representation) and deriving more advanced game objects by adding functionality or specialization to the derived game object. It should be noted that even entities, such as the ground to walk on or water, might be implemented as a single or collection of game objects. For environmental effects such as lighting or heat, that have a source, but where only the effect is modeled, the effect is often attributed to the environment, for example, the sun produces heat, but the sun is not modeled, only the effect of temperature on other game objects. A world will contain both ephemeral things, such as spoken words, and nonephemeral things, such as rigid bodies. Supporting the nonephemeral requires the world to support P.

Things or Phenomena requires: SA.

Many Human Agents (HA) An environment with exactly zero (ZERO) humans can be considered and would be the likeness of a pure simulation, for example, an MUD where no players ever connect. Examining for support of one, two, three, four . . . and an increasing amount of humans leads to a subjective debate on how many humans is enough for an environment to be considered a virtual world, for example, R. A. Bartle (2010) estimates that 100,000 players would be enough to constitute a massive world by today's standards. This property is generalized as support for MANY HA.

Many Software Agents (SA) Because a virtual world is a simulation, one can attempt to simulate HA. Van de Velde (1995, original italics) states that "The concept of *agent* refers to a system that can be differentiated from its environment and is capable of direct and continued interaction with that environment. Such a system 'exists' in its environment and has with it an observable interaction, which is called its *behavior.*" Shoham (1997, pp.271–272) has defined a *software agent* to be one "that functions continuously and autonomously in an environment in which other processes take place and other agents exist. [. . .] The sense of 'autonomy' is not precise, but the term is taken to mean that the agents' activities do not require constant human guidance or intervention." If VT is supported, agents that activate at a regular interval are considered running continuously. It is possible to run agents off other temporalities, but in order to be able to persist the state of the agent and maintain a pure virtual world (contrary to mixed reality), VT is required. According to Russell and Norvig (2010, p.39), an agent that lacks autonomy "relies on the prior knowledge of its designer rather than on its own percepts [. . .] A rational agent should be autonomous – it should learn what it can to compensate for partial or incorrect prior knowledge," that is, autonomy assumes learning. The more relaxed definition of an autonomous agent, by Shoham (1997), is adopted here which does not assume learning. According to Russell and Norvig (2010, p. 39), the most simple agents possible are simple reflex agents, which "select actions on the basis of the current percept, ignoring the rest of the percept history." It is through SA that if a virtual world has ZERO users, the simulation will produce events, that is, develop internally.

Software Agents requires: VT.

Virtual Interaction (Ix) "The concept of 'interaction' generally means 'exchange', 'interplay', or 'mutual influence'" (Qvortrup 2001, p. 34). It is important to make the distinction between the exchange of interaction and the "to act upon" or "react to a stimulus," for example, users act upon user interface entities and a player might react to the stimulus of heat or gravity. In order for exchange to be possible, agents other than humans must be capable of interaction, with for example, SA. This property means the user can both interact with people (Girvan 2013) (other HA in the virtual world) and "interact" with the world (Girvan 2013; R. A. Bartle 2010) (interact with SA and act/react to things and the environment). Both the "a way to communicate" and "a way to share," referred to by Singhal and Zyda (1999, p. 3), is not handled separately, but categorized here under Ix.

If two virtual entities are to have interaction, they must have virtual proximity (Qvortrup 2001), requiring both the 1S and 1T from above, that is, they must share at least one abstraction of time and 1Sh.

Virtual Interaction requires: SA, 1S, 1T, and 1Sh.

Nonpausable (nZ) There is a subset of Rt games that have an "active pause system" (Wikipedia 2015b). For games that support VT, this means players (operators should be able to pause the system for maintenance) can actively choose to freeze VT relative to real-world time. For nZ, technologies are examined for the **absence** of an active pause. Bell and Robbins-Bell (2008) consider the nZ property as a part of P.

Nonpausable requires: Rt.

Persistence (P) R. Bartle (2003) states that a persistent virtual world "continues to exist and develop internally even when there are no people interacting with it." The criterion that a virtual world should "develop internally" is handled by

SA, which constantly alter the world (e.g., as in MUD0). Later, Bartle revised his persistence criterion, removing the need for internal development, stating: "if you stop playing then come back later, the virtual world will have continued to exist in your absence" (Bartle 2010). Bell and Robbins-Bell (2008) use Bartle's original criterion, but interpret persistence to differentiate between video games and virtual worlds on the basis that "a virtual world cannot be paused." Pausing is handled by nZ. Bartle's criterion that the world must "continues to exist" can be referred to as *world persistence* (Nevelsteen 2015), that is, the world continues to exist and is available to the players when they want to access it. To ensure world data is not lost in the event of system failure, the system must support *data persistence* (Nevelsteen 2015).

It is also possible to discuss persistence of the game from a cultural perspective (e.g., events and activities in the game world which do not "reset" (Keegan 1997; Brennan 2009) or are not interrupted by real-world events, like bathroom breaks), but these concepts are beyond the perspective of this article.

The problem with world persistence is that it can be simulated (i.e., pseudo-persistence (Söderlund 2009)), without raising awareness to the player. If the world is made available to players at all times they want to access it, it is seemingly always in existence; a straightforward way to achieve this is to have scheduled play times around down times (Nevelsteen 2015). World data can be loaded and made available at specific times when players, relevant to that data, are playing (Söderlund 2009). In a single-player game, events can be generated to simulate the passing of time during which the game was actually shutdown (Wikipedia 2015a; Nevelsteen 2015). A straightforward way to avoid needing data persistence is to simply have no data to keep track of.

VT is precisely what allows the loaded state to be persisted to storage and reloaded easily; without the abstraction, the world's time would freeze during storage, suddenly rewinding on a rollback or fast-forwarding to the current real-world time on load. Hybridity is possible, but then the world is mixed reality.

Many Avatar (Av) Described as "extensions of ourselves" (Qvortrup 2001, p. 26), there are many definitions of the term "avatar." R. A. Bartle (2010) describes an avatar as a "virtual self" where "each player identifies with a unique entity within the virtual world (their character) through which all their in-world activity is channelled." According to Bell and Robbins-Bell (2008), "any digital representation (graphical or textual), beyond a simple label or name, that has agency (an ability to perform actions), presence, and is controlled by a human agent in real time is an avatar." The real-time aspect is handled by Rt. There is ambiguity in the situation where a user, in a single-user environment, has an ego-referenced viewpoint (e.g., in Zork (Supnik et al. 2003), where the player cannot look at themselves, or in some first-person perspectives in 3D environments); if no digital representation is present, do they actually have one? Even without an avatar, SA must be able to react to the presence of the user, that is, some entity. In this regard, R. A. Bartle's definition of the virtual self is superior to that of Bell and Robbins-Bell (2008), since it defines an entity through which presence can be detected and interacted with, rather than a graphical or textual representation.

Although it is often true that virtual worlds assign a unique virtual self to the user, there is evidence that this is not a requirement. For example, in WoW, there are users that purchase multiple accounts and control multiple avatars simultaneously through multiple installations of the game, a technique that has been referred to as "multiboxing" (WowWiki.com 2015). Because multiboxing can be used to override the unique avatar feature of WoW, the definition by R. A. Bartle (2010) shall be used here, but without the uniqueness criterion.

Drawing Conclusions

The aim of this work is not to express a value of how virtual-like or world-like a virtual world is,

but to find a definition that delineates what is and is not a virtual world, for example, a 3D virtual world with multiple players, a vast many places to visit, totally immersing each player might feel much more worldly than an MUD, but the definition should not exclude an MUD from being a virtual world. In this section, all properties are assembled into the definition herein.

Real-Time Shared Spatiotemporal VE VT ensures the world has its own time, independent from other times. A virtual world can be built based on ST (without VT), but all events related to ST are subjected to be rewound or fast-forwarded, in the case of rollbacks or downtime, respectively. Such a world, however, would not be purely virtual. VT works together with P, ensuring that events persisted to disk are independent of ST, that is, VT can be translated along the timeline relative to real-world or ST, without effecting time-based in-game events. The Rt property excludes turn-based, tick-based, and any other technologies that do not allow users to simultaneous interact with the world. 1T and 1S ensure that the VE conforms to a spatial representation with the likeness of a world and that it is shared by the user of that world.

Shared Spatiality Within One Shard If a technology has more than one data space, 1Sh dictates that those spaces must be merged at one point or another for them to be considered one virtual world; each other copy/shard is considered another world. The question at hand is how to deal with instances, that is, are they part of the virtual world or not? A solution is to judge each shard on its own merits as to whether it classifies as a virtual world or not. An instance can be considered a temporary shard (a copy of a space to which a group of players is assigned), but not a virtual world, if it does not support the required properties, for example, P. In Diablo (Blizzard Entertainment 1996), the virtual lobby is not a virtual world, because it lacks properties such as VS. And the world instances are not virtual worlds either. If the world instance would constantly synchronize with the virtual lobby, the lobby would be providing P for the instance. It is specifically the 1Sh property that allows for a virtual world to be divided in a distributed system, but still remain one world. 1S and 1Sh are combined to determine if technologies have a shared spatiality captured within ONE shard.

Interacting Agents and Things Most technologies support MANY HA outside a pure simulation of a world. R. Bartle's criteria states that a persistent virtual world "continues to exist and develop internally even when there are no people interacting with it." From this, it can be ascertained that the world must support ZERO humans, that is, a world that suddenly has no people connected to does not loose its worldliness. This allows for a virtual world to be created for dogs or other nonhumans. And also, if a world is to continue to develop internally with ZERO humans, the world must support entities that can take action, that is, support for SA determines if there is enough potential intelligence in the system to cause sufficient worldly change. Combined with Ix and the shared temporal space from above, this means humans can potentially virtually interact, in the same time and space, with other HA or SA, or act/react to things and the environment. A technology that just supports HA is a communication technology, but not necessarily a virtual world.

Persistent Virtual World P ensures the world is available to the user when they wanted to access it and where non-ephemeral changes in the world were preserved. P combined with the shared spatiotemporal environment from above ensures that the environment is not a fleeting transient event. To satisfy the criteria by R. Bartle (2003), P is combined with SA. To satisfy the criteria by Bell and Robbins-Bell (2008), P is combined with nZ, a property that seems to effectively segregate virtual worlds from video games, when combined with P. The result of the combination is a real-time environment that is nonpausable where agents produce lasting change.

Virtual Self as Avatar Singhal and Zyda (1999) define a net-VE as a multiuser environment, with each user represented as an avatar; users need a representation through which other users can detect presence and interact. Although it might simplify the definition, no assumption is made here that a virtual world is required to be multiuser, so a single-user environment is still acceptable. The uniqueness criterion for a virtual self has been dismissed on the grounds that multiboxing does not alter the worldliness of a virtual world.; Av is the virtual entity which R. A. Bartle has defined as a "virtual self," with the uniqueness constraint dropped, so that agents (HA or SA) have something to interact with. If MANY avatars are present, at least one avatar must be present in the shared spatiotemporal environment from above.

Discussion and Conclusion

Properties not used can instead perhaps be use to distinguish between different virtual worlds, rather than classify a virtual world. Girvan (2013) offers the properties: "3D, educational, goal orientated, graphical and user-generated content." Some additional properties not mentioned in the analysis are number of players, theme (e.g., fantasy, science fiction), strategy type (e.g., RPG, PvE, PvP), and in-game communication possibilities (e.g., chat, VoIP).

Milgram and Colquhoun (1999) present a continuum for mixed reality, between the virtual and physical. If the VT, VS, SA, Ix, or Av have been "mapped" to a physical counterpart, then the world should fall on the continuum in between the pure virtual and physical. Note that because WoW makes use of both ST (e.g., for the day/night schedule) and VT, to be precise, that would make WoW not purely virtual, that is, a mixed world.

If the provided definition herein proves to not be future proof, properties can be added and the definition can be updated to classify future technologies.

Definition

Visual accessibility in computer games refers to techniques used to convey or enhance understanding of visual information, particularly for blind or partially sighted individuals. Visual information describes any narrative or gameplay information which is conveyed to the player in a visual format such as text or images displayed on a screen.

Introduction

Over the years, computer games have become an increasingly popular form of entertainment (Cairns et al. 2019). Games have the capacity to connect people across the world whether they are playing together in a multiplayer environment or discussing their varied experiences of a single player game. However, despite the increased popularity of games, many of them remain inaccessible to large portions of the population (Cairns et al. 2019). There are many factors which may make games inaccessible to users ranging from controller design to reliance on visually conveyed information ("Game accessibility guidelines" 2012). Games are intended to be enjoyed by as many players as possible, and when accessibility concerns prevent players from playing a game, it is the responsibility of developers to continue to improve and iterate on their designs to overcome these obstacles so that everyone is included (Cairns et al. 2019). Many accessibility options exist and the field of accessibility has received increased attention in recent years from both game development studios and games user researchers (Cairns et al. 2019). This increased attention has led to further innovations and the development of new accessibility options to overcome a variety of obstacles (Cimolino et al. 2021).

The adoption of these accessibility options varies considerably across the games industry (Porter and Kientz 2013). Despite the existence of these options, many games continue to prove inaccessible to players (Kulik et al. 2021). Conversely, some games focus extensively on accessibility and push the boundaries of current accessibility options by developing new options or refining existing options (Morris 2021; Ombler 2021). In the case of visual impairment, key developments in accessibility have focused on relaying visual information through sound with spatial audio and narrative descriptions, and touch with haptic feedback (Fiadotau 2018; Kelly and Şengün 2022; Stevens 2018). Additionally, accessibility options vary depending on the hardware and software available to players based on whether they are playing games on a dedicated gaming console or a computer. Computers offer additional software options such as screen readers, but these programs are not always compatible with games and require additional attention for compatibility. Fortunately, in recent years, there has been an increased focus on making games more compatible with assistive technologies such as screen readers so that players can continue to rely on these tools as they play. Alternatively, consoles readily provide haptic feedback through game controllers, but this option can also be acquired for computer games with a compatible gamepad controller.

Spatial Audio

Spatial audio refers to audio processing algorithms which deliver sound-based cues in a way that reflects a three-dimensional (3D) environment (Yadegari et al. 2022). This method of providing the information is especially useful for visual accessibility. This spatial audio application has recently been explored on consoles in *The Last of Us: Part II* (Kelly and Şengün 2022). In this game, players can detect enemies in their environment with a system similar to echolocation. Players make a ping centered on their location, which expands and returns as it hits characters in the environment (Ombler 2021). Depending on where these enemies are located in relation to the player, the position of the returning ping in the soundscape will change to indicate direction, and its pitch will change to indicate the distance. In this way, players know how many enemies are in their vicinity, whether they are near or far, and whether enemies are above, below, or on the same level as the player

(Ombler 2021). Given the importance of precise player and enemy positions across many genres of games, conveying this information in a variety of ways is vital to ensure that games remain accessible to players with visual impairments.

In computer games, a recent example of advances in the development of spatial audio can be found in *The Vale: Shadow of the Crown* (Reeves 2021). In this game, Unity tools originally developed to create spatial audio for virtual reality (VR) games are leveraged to create "3D soundscapes" (Reeves 2021). Taking this a step further, *The Vale: Shadow of the Crown* forgoes the use of visuals entirely and instead uses spatial audio to immerse players in the environment and convey vital information for gameplay such as the timing of enemy attacks. Spatial audio has a diverse range of applications, and given the recency of this development as an accessibility tool, it is an area which warrants further research to determine new applications and refine existing ones.

Narrative Description

Narrative description is another method used for conveying information in a visually accessible way and refers to any form of visual accessibility which relies on delivering narrative information through speech or other forms of audio. Depending on the needs of the game being developed, there are multiple ways for narrative descriptions to be implemented. Two of the core methods for this are audiogames and described audio.

Audiogames

An audiogame is any game that forgoes the use of visuals and instead relies entirely upon audio to deliver information (Fiadotau 2018). Some methods of delivering information solely with audio include voice-acted dialogue, spatial audio, and describing game elements with a narrator rather than text captioning (Fiadotau 2018). One recent example of an audiogame is *The Vale: Shadow of the Crown* (Morris 2021). In this game, the only visual displayed on the player's screen during gameplay is a set of floating lights in an abstract background which has no relation to any of the game's content (Morris 2021). The narrative is entirely voiced, and spatial audio is used to immerse the player (Morris 2021; Reeves 2021). On the main menu, selectable options are displayed in text, but they are also read to the player whenever the option is being interacted with, and, while playing the game, interactions such as movement and swinging weapons are described to the player along with the actions the player must take to perform them.

Given that audiogames rely solely on audio, all of the systems present in these games must revolve around creative uses of game audio. The audiogame approach of audio first rather than visuals followed by visual accessibility options to translate that experience into audio has the potential to create more dynamic experiences for blind and partially sighted users. However, it is vital that these games' development is guided with input from the blind and partially sighted community to account for the biases of sighted developers and ensure that the intended experience is delivered (Morris 2021). In the case of *The Vale: Shadow of the Crown*, this was accomplished through a collaboration with the *Canadian National Institute for the Blind* (CNIB) (Morris 2021).

Audio Description

Audio description (AD) is the practice of having a narrative describe visually displayed elements of a scene in words so that blind or partially sighted users can experience the full range of information in a scene. Many games rely upon a mixture of audio and visual information, and, in these cases, AD is an effective method for ensuring that all players have equal access to this information (IGDA GASIG 2020). While AD has not yet been adopted as a common strategy for visual accessibility by game developers, community-driven movements have stepped in to fill the gap (IGDA GASIG 2020). Notably, *The Transcribing Games Project* is working on creating AD transcript guides for cutscenes and various encounters in a variety of games, including *God of War* and the *Gears of War* franchise (SightlessKombat

2022). This initiative aims to demonstrate the efficacy of AD as an option for visual accessibility with the hope that it will be adopted in the games industry similarly to how it has already been adopted as a standard accessibility option in film and television (IGDA GASIG 2020). Interest in audio description for games is still in the early stages, but with some large studios beginning to take an interest, this may grow to become a part of visual accessibility in games in coming years (IGDA GASIG 2020).

Despite the many potential benefits of AD, these benefits are based entirely on how effectively the AD is created and delivered (IGDA GASIG 2020). For example, with the wrong tone or word choice, the meaning of visual elements in a scene may be transformed in their translation into AD and the message the player takes from the scene may differ from what was intended or the player may miss out on vital information. As such, it is important that audio description be thoroughly tested throughout the design process and that user testing is guided by the experience of blind and partially sighted users (IGDA GASIG 2020). As in all cases of accessibility, companies must work with and learn from the experience of members of the communities which these options are intended to support.

Software Accessibility

There are many different types of software developed for the purpose of accessibility, allowing a user to create a more personalized experience to assist in overcoming any obstacles they may come across when using various forms of computer software. Here, we will explore some of the types of programs developed for visual accessibility, along with some of the limitations and difficulties that can occur when using them or developing them.

Screen Readers

Many software tools exist to assist people with visual impairments that can and are used with video games. Some of the most notable tools in this area are screen readers. This type of software is able to read the text provided by web browsers, email clients, and other computer software and output them to the user, usually as audio or by text to a braille reader (American Foundation for the Blind 2020). Currently, there is a trade-off when adding user interface (UI)-text-to-speech features to the software. There are APIs dedicated to feeding text to third-party screen readers that games can access on desktop platforms, such as the. NET UI Automation API (Microsoft 2021) and the OS X Accessibility API (Apple 2015). However, not all platforms have such dedicated systems. As such, developers should consider what platforms they are developing for and investigate existing interfaces that can be leveraged for each platform in both hardware and software before attempting to create in-house solutions.

It is important to consider design principles to ensure compatibility with various platform specific software and the effectiveness of designs in delivering accessible user experiences. *Microsoft*, for example, has created official guidelines for ensuring effectiveness and compatibility with external screen readers (Microsoft 2021). These guidelines provide recommendations on introductory principles of what elements should be included as well as when and how they should be implemented (Microsoft 2021). There are many kinds of user interface elements, but perhaps the most important guidance that can be provided is to include text alternatives to describe each UI element's functionality. For other objects, such as images or icons, it is unnecessary to describe the type of object being selected, and developers can instead focus on describing the function of each element. Accordingly, for any UI elements made with a markup language, developers should ensure that the IDs and attributes of each object are unique. These unique identifiers will then help assistive technologies track changes to existing objects.

Magnifiers

It is important to note that visual impairment has many dimensions, such as acuity and color, and depth of field. Accordingly, software-based vision aids are frequently used in visual accessibility to accommodate the wide range of experiences

associated with visual impairments. One such feature is magnification software (American Foundation for the Blind 2020). With this software, users can select a region on their screen to increase the size of visual elements within so that they become easier to read. Magnifiers are available as a standard option on most desktop platforms and can be used in conjunction with gaming software (Microsoft 2022a, b; Apple 2020). Frequently, magnifying software will require the game to be in a windowless fullscreen or windowed mode to not interfere with game input. While it is always advisable to have in-game text size be variable for player preference, this is another option that can assist in making a game more accessible.

Color and Contrast

Another feature that comes standard on most desktop platforms is color filtering (Microsoft 2022a, b; Apple 2020). Filters change the colors on a screen to a palette specifically designed to make information displayed on the screen more readable for people with the type of color blindness for which the filter is designed. However, some platforms may not have built-in color filters, and developers should take care to check what features are already available on the platforms they are deploying to before considering creating an in-house solution.

Hardware Accessibility: Haptic Feedback

While the previously mentioned features have all been related to software, hardware can also be leveraged to make games more visually accessible. Haptic feedback refers to any kind of feedback conveyed through a sense of touch. Within gaming, this is almost always in reference to a rumble feature on a gamepad, though a few other options exist, such as gamepads that can alter the resistance of certain buttons when pressed (Gartenberg 2021). Haptic feedback is not commonly featured on personal computers that are utilized through mouse and keyboard. There are some mice that include a rumble feature, but these are uncommon. To utilize haptic features on a computer, the best option is to connect a compatible gamepad controller since rumble is a standard feature of these devices.

Given that haptic feedback can be utilized by players who have either limited vision, hearing or both, it can be a valuable tool for providing information to players (Stevens 2018). By altering the pattern and strength of a rumble, a game can provide contextual information such as impending enemy attacks or critically low player health. However, some haptic feedback, like rumbling, can be uncomfortable, distracting, and potentially even painful for some players, so it is necessary to have an option to turn this feature off.

Conclusion and Discussion

There are many different options for making games more accessible for players with visual impairments, but these options are applied inconsistently throughout the games industry (Porter and Kientz 2013). Options all have their specific uses and limitations that should be considered during the game development process to ensure that the final product is accessible to as many players as possible. To ensure that games are as inclusive as possible, developers must learn from established research in accessibility, seek out feedback from players with disabilities, and collaborate with the communities aiming to make their games accessible at every step of the game design process.

Definition

A visual novel is a form of digital entertainment that consists of text accompanied by mostly static graphics. The reader advances the text, usually by clicking, and is occasionally presented with choices, which may or may not affect the outcome of the story. Despite originating from Japan, visual novels have gained some international recognition, although it remains debatable whether or not they should be classified as video games.

Overview

"Visual novel" is a term that is more popular in the West than in Japan where the genre originates from. In Japan, visual novels are often called *noberugēmu* ("novel game," short for "visual novel game") and, occasionally, *saundonoberu* (sound novels), the latter being a term introduced by game company Chunsoft, which in the early 1990s developed a series of such games for the Super Nintendo Entertainment System. Prior to that, visual novels were developed almost exclusively for the personal computer, which still remains the platform of choice for many visual novel developers.

In Japan, visual novels are often considered a subgenre of adventure games (Koyama 2006: 31). However, due to their reliance on textual narrative which is affected by the reader's choices, visual novels are also close to Choose Your Own Adventure books and, more broadly, can be considered a form of interactive fiction (Yin et al. 2012). However, they have also evolved distinct conventions that set them apart from other similar genres.

One easily recognizable feature is the visual presentation, with most visual novels utilizing a first-person perspective and featuring static or sparsely animated nonplayer characters displayed against an equally static background. Backgrounds represent particular locations within the game world and change as the player character moves about (Galbraith 2011). The dialogue and narrative take the form of text, either overlaying the graphics or displayed in a text-box occupying the bottom part of screen. While their visual style can range from photographic to pixel art, the majority of visual novels favor anime-style esthetics (Bruno 2017) (Fig. 1).

Visual novels also have a less straightforward relationship with player choices than most works of interactive fiction. Whereas in a Choose Your Own Adventure book each choice can shift the story dramatically, choices in a visual novel may have no immediate effect on the narrative, contributing instead to a complex system of potentialities and character relationships that resolves itself toward the end (Fiadotau 2018). For example, in the beginning of *Ever 17: Out of Infinity* (2002), the player, put in the shoes of a visitor to an underwater theme park, is given the choice of either listening to the safety briefing offered by a staffer or listening to a joke told by a fellow visitor, thereby missing the staffer's explanation. While the choice has very little immediate effect, ignoring the joke may prevent the player from reaching the "true" ending of the game due to failing to establish rapport with the fellow visitor.

The existence of multiple endings and especially a "true" ending, which is typically only unlockable after several or all of the other endings have been reached, is another notable feature of visual novels. *428: Fuusa Sareta Shibuya de*

Visual Novel, Fig. 1 A scene from Ever 17: Out of Infinity (2002), featuring typical visual novel elements: static background, anime-style characters, and a text box in the bottom part of the screen

(2008), for example, has a total of 85 endings, only 1 of which is considered the "true" end. On the other hand, some visual novels, such as *Planetarian: Chiisana Hoshi no Yume* (2004), feature no choices at all and are completely linear, therefore only having one possible ending. These are known as "kinetic novels" (Fiadotau 2018), so named after a series of linear visual novels produced by Japanese game company VisualArt's (Fig. 2).

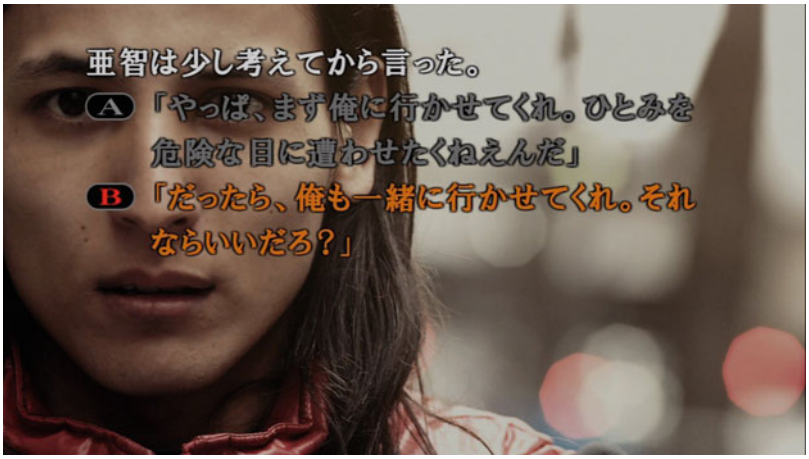
Many visual novels focus on romance, often containing erotic or pornographic elements (Bruno 2017). A particular subset of visual novels, known as *bishōjo* (lit. "beautiful girls") games, feature a male protagonist romancing one of several female love interests, typically culminating in an erotic scene (Sousa 2014). Other visual novels adopt a female perspective on romance (*otome*) or depict male-on-male (*yaoi*) or female-on-female (*yuri*) homoerotic relationships, although these are generally tailored to the tastes of a heterosexual audience (Arunrangsiwed 2015; Nagaike 2010). Some visual novels, such as *Eve: Burst Error* (1995) and *Air* (2001), have been released in two versions, with and without sexual content, in an effort to broaden their appeal. Even when romance is not the central theme, visual novels tend to place a lot of emphasis on communication and building relationships with characters (Bruno 2017).

On a wider level, visual novels, and especially *bishōjo* and *otome* games, are often seen in Japan as part of the *otaku* subculture, which revolves around conspicuous, often defiant consumption of popular culture such as anime, manga comics, and TV series (Sousa 2014; Galbraith 2011).

Significance and Impact

While usually associated with Japan, visual novels have had considerable influence beyond their country of origin. Titles such as *Ever 17: Out of Infinity* (2002), *Clannad* (2004), and *Rewrite* (2011) have been translated into a number of languages, including English, and achieved popularity abroad. This has led to the emergence of original Western visual novels such as *Digital: A Love Story* (2010) and *Everlasting Summer* (2014). Visual novels' focus on choices and relationship building has also inspired Western adventure game developers such as Telltale Games to depart from the conventions of point-and-click adventure games and experiment with more narrative- and character-driven game design (Gravelle 2016).

However, a fundamental question visual novels have raised in the West is whether they should be classified as games at all (Heron 2013: 58). In Japan, visual novels are generally accepted to be



Visual Novel, Fig. 2 In 428: Fuusa Sareta Shibuya de, the player has to make many choices, which can result in a total of 85 endings

a genre of computer games and are in fact called that ("novel games"). Western audiences, however, remain split over the question of whether an occasional choice constitutes enough interactivity to call something a video game. The case of kinetic novels, which have no choices at all, complicates the issue even further – although the absence of choices is not necessarily immediately obvious to the player (Fiadotau 2018). This ambiguity suggests that the notion of a video game is not universal and may be culturally conditioned.

Whether or not visual novels as such are games, they combine well with other game genres. Many popular titles in Japan include story-driven visual novel segments interspersed with puzzles (*Nine Hours, Nine Persons, Nine Doors*), fighting (*Melty Blood*), role-playing (*Princess Waltz*), rhythm gaming (*Symphonic Rain*), and so on.

Due to their simple mechanics, visual novels are also relatively easy to develop. As a result, the genre is very popular with hobbyist (*dōjin*) game developers in Japan (Picard 2013) and is used by indie developers in the West as well.

This ease of development, coupled with the genre's emphasis on textual content, makes visual novels a good vehicle for learning. Commercially released visual novels that incorporate educational elements include *Emit* (marketed as a game for learning English) and *World End Economica* (which introduces many concepts in economics despite not being positioned as an educational game). The visual novel genre has also been adopted by serious games whose purposes range from increasing hospital patients' self-efficacy (Yin et al. 2012) to promoting tourism in rural areas (Kurata 2013). This shows that the range of possible applications of visual novels as a medium reaches far beyond the cultural niche the genre has originated from.

Definitions

Volumetric filmmaking is an application of volumetric capture technology to filmmaking. Volumetric recording captures the topology of objects in 3D space rather than the projection of 3D space onto a 2D frame. The recording can be viewed from any perspective decided by the viewer at the time of viewing. Thus, in volumetric film, the viewer takes over the director's responsibility for

selecting the *point of view* from which the story is being told.

Introduction

Volumetric filmmaking is an interactive, participatory, and narrative medium enriching the vocabulary and grammar of audiovisual storytelling. Volumetric filmmaking is made possible by the development and democratization of access to volumetric capture technology. Volumetric capture is a recording of topology, rather than a 2D projection, of actors, sets, props, objects, and environments. Volumetric filmmaking is not just a technological innovation, but a new-in-kind audiovisual medium since it changes the role of the director and empowers the viewer in the process of telling and absorbing the story. In traditional 2D and 3D filmmaking, the story is told through a carefully arranged sequence of 2D projections called "frames." In 360 immersive video, the story progresses through series of predetermined spherical projections of the film world. In volumetric filmmaking, the position of the sphere through which the viewer perceives the story is decided by the interaction performed by the viewer at the time of the viewing (Fig. 1). The fact that the viewer is in control of the sphere's position makes volumetric filmmaking a new-in-kind medium.

The first volumetric captures for entertainment date back to 2006, when a point cloud of Thom Yorke of Radiohead was used in a music video for his "House of Cards" song Yorke (2008). In recent years, a diversity of volumetric experiences were created, including Oscar-winning "Carne y Arena" by Alejandro Gonzlez Irritu Irritu (2018), Emmy-winning "Zero Days VR" volumetric documentary film by Yasmin Elayat Elayat (2017), "Terminal 3" by Asad Malik Malik (2018), or interactive fiction narratives such as "Vera" by Krzysztof Pietroszek Pietroszek (2020). Currently, the volumetric filmmaking enters its Renaissance age due to the volumetric capture technology becoming more accessible to filmmakers.

Technology of Capturing Volumetric Data

Despite the name, the volumetric capture used in volumetric filmmaking does not capture the object's volume per se. While technologies such as magnetic resonance imagining or computer tomography allow for capture of the volume of many types of objects, these techniques are not used in volumetric filmmaking due to cost and associated health risks. Rather, volumetric capture records the information about the *topology* of the captured object or person, without any

Volumetric Filmmaking, Fig. 1 Traditional vs. 360 Video vs. Volumetric Filmmaking. In traditional filmmaking, the story is told through a sequence of frames (left). In 360 video, the story is told as a series of static spheres surrounding the viewers (center). In volumetric filmmaking, the sphere is moving at the direction of the viewer (right)

information about the interior. The reconstruction of the topology utilizes two types of techniques: photogrammetry or depth sensing. In practice, photogrammetry is often used for volumetric capture of static objects, such as film sets and props, while depth sensors are used for capture of moving objects or actors.

Capturing Static Objects

Photogrammetry process results in high quality 3D reconstruction at relatively low cost, since the capture can be performed by a single digital photography camera. The process consists of systematically taking many (often hundreds of) photos of uniformly lit object from various angles and at various distances from the object. The setup requires fast shutter (at least 1/250 for handheld capture) and small aperture (at least 1/8 on a typical DSLR) since the goal is to capture images of the object without motion blur or shallow depth of field.

If the object is small enough, it can be placed on a turntable with the camera taking photos at predefined angle intervals corresponding to the object rotation, for example, every two degrees. If the object is larger (e.g., an interior location), digital camera is used to take hundreds of photos from various perspectives. For extremely large objects, such as entire buildings or towns, when taking individual photos is impractical, drone flights can be performed with the camera recording a film, rather than taking individual photos. Using the velocity and the position information about the drone flight to aid the reconstruction of the object improves the reconstruction process. This approach to photogrammetry is called *structure-from-motion.*

Not all objects can be efficiently captured with the process of photogrammetry. Objects that are shiny, and therefore show specular reflections, are difficult to capture. Transparent or semitransparent objects that diffract the light cannot be captured with the photogrammetry method at all.

Most of the photogrammetry reconstruction algorithms take both angle between a pair of images and the color of each pixel in both into account, thus objects with pattern or texture tend to be reconstructed with higher precision. Objects with predominantly convex topology are reconstructed with less error, since the reconstruction algorithms may have difficulties or are incapable of inferring occluded or concave areas of the object, if no sufficient information can be derived from the series of photographs taken.

Many commercial as well as some open-source solutions exist to assist in photogrammetry process Hanke and Grussenmeyer (2002), Spurr (1960). The process of photogrammetry is very computationally intensive, since typically each image is compared, pixel by pixel (or small region of pixels by small region of pixels), with all other images in the series. Until recently, the photogrammetry process could take days on a typical PC. Since the implementation of GPU-compute-shader-based photogrammetry algorithms, the process now takes minutes or hours.

Alternatively to photogrammetry, a static object can be reconstructed using 3D scanner. Laser-based (LIDAR) 3D scanners provide the highest reconstruction quality at high cost. Handheld laser or infrared 3D scanners result in topology reconstruction of the quality similar to or better than photogrammetry but are usually used to reconstruct the object's shape only, without color. Finally, handheld depth cameras, such as each generation of Microsoft Kinect, can be used for 3D scanning and reconstruction, but the resulting object is usually reconstructed with the lower quality than through the photogrammetry process.

The reconstruction resulting from photogrammetry or 3D scanning requires further processing to be used in volumetric film. First, since the reconstructed mesh usually consists of hundreds of millions of vertices, it must be decimated. In case of complex typologies, the standard decimation process may not be sufficient or may introduce topological errors, in which case, a 3D modeler may choose to perform manual retopology of the object. If the object is not uniformly lit (for example, part of the object is in a shadow), a delighting process may also be performed on the object's texture, so that the resulting reconstruction can be properly lighted in the film scene where the object is used.

Capturing Moving Objects

Both photogrammetry and 3D scanning processes, when performed with a single sensor, require the object to be static for the entirety of capture. In consequence, while the techniques result in high-quality reconstruction, they cannot be used in practice for capturing actors or moving objects. To capture actors and moving objects, a system of multiple cameras is used. Since more cameras produce more data and increase the overall cost of the system, low-cost-low-quality volumetric capture systems tend to use fewer cameras (from 1 to 20), while high-cost-high-quality systems use many cameras (from 30 to over 100) and produce petabytes of data.

There exist commercially available low-cost volumetric capture systems that offer a capability of capturing volumetric data of acting performances, or, more generally, moving objects, using a single RGBD sensor (aka depth camera), such as Microsoft Kinect or Moholo camera. Single depth camera recording results in a volumetric capture that can be viewed only from a limited sweet spot of about 10–20 degrees off the angle of the recording. With the advent of a new generation of better quality RGBD cameras, research and development efforts are put toward creating low-cost multicamera capture, and it can be expected that such systems will be widely available in the near future. Current depth camera errors are the main limitation of the RGBD-based approach to multicamera volumetric capture, since it is difficult to register multiple cameras to each other when the pixel positions differ by such a large error.

In RGBD sensors, two technologies are commonly used to infer the 3D position of the pixels: *structured light* and *time of flight.* Both technologies use infrared light instead of visible spectrum light. Structured light entails a specific pattern projected by the camera onto the surface to be captured. Then, the same camera records back the pattern and infers the surfaces' topology from the pattern's deformation. While the technique is easy to implement in a low-cost hardware (e.g., Kinect 360), the pattern deformation does not provide enough information for high-quality reconstruction. Additionally, the pattern projection is prone to errors resulting from environment lighting and the distance of the object from the camera. The second approach, time-of-flight, measures how much time it takes for the photons of the light emitted by the camera to return back to the camera after being reflected by the surface to be captured. This technique results in smaller error that does not increase with the distance from the camera as quickly as it was in the case for the structured light technique. Nevertheless, the technique suffers from errors on edges of the captured objects, because the angle of reflection results in no photons coming back to the sensor. The technique is also sensitive to environmental lighting conditions, when, for example, sunlight floods the scene with infrared light that confuses the sensor.

High-quality, but much more expensive commercial volumetric capture systems, such as Microsoft Meta Stage, or Intel Volumetric Studios, typically utilize an array of tens or hundreds of time-synchronized RGB cameras, thus avoiding the issue of depth-sensor error. The process used in reconstruction of volumetric images from multiple RGB cameras is no different than static photogrammetry and results in individual reconstructions of 3D objects for every frame, typically 30 frames per second. The resulting series of 3D reconstructions, when played as a film, often create a flickering visual artifact, because reconstruction of each frame is done independently from all preceding and following frames. Some researchers are attempting to improve time coherence of the resulting point clouds or meshes, thus addressing the flickering issue.

Serialization

Regardless of the technique used, the resulting volumetric recording is a static or temporal textured mesh. The mesh can be serialized in traditional 3D modeling formats, such as a series of Wavefront Technologies' .obj files. Since separate mesh and texture are recorded for every frame of the volumetric recording, this approach results in very large data, making it impractical for streaming or mobile applications. An interesting approach to this problem is to encode the capture

Volumetric Filmmaking, Fig. 2 Volumetric capture video frame: The top part of the frame provides the rgb information, while the bottom encodes depth information for each pixel of the captured scene

for each camera as a top-and-bottom color video file where the top of the frame provides the rgb information and the bottom of the frame provides matching depth information. This approach is particularly effective for single camera volumetric captures that do not capture the information about all the sides of the object (Fig. 2).

Viewing Volumetric Captures

Rather than project a traditional video recording that captures a projection of three-dimensional reality onto a two-dimensional frame and presents the results in a series of frames in juxtaposition to achieve the desired narrative, volumetric filmmaking seeks to capture and present three-dimensional data on actors, props, and set decoration and presents it as recorded. The way the volumetric recording technology captures and represents reality affects the way the volumetric story is/should/has to be told. Interestingly, regardless of the quality of capture, the playback of volumetric recording does not seem to cause the "uncanny valley effect" (Mori et al. 1970).

Volumetric film can be presented at any point of the reality-virtuality continuum. The films are typically experienced using a head-mounted display, mixed-reality glasses, or through a magic window of a mobile device, but stand-alone multiviewer volumetric displays also do exist. Large-scale multiviewer presentation is also possible using CAVE systems, or transparent foil projection. Fog displays combined with projection mapping allow for large-scale multiangle volumetric viewing but offer low visual fidelity.

Depending on the type of display used, volumetric films may be viewed at a wide range of scales, from miniature to life-size. Current limitation in the field of view (FOV) of augmented reality displays pushed volumetric filmmakers to search for meaningful, smaller than life-size presentation scales. One idea is to present miniature experience on a tabletop https://www.rsc.org.uk/events/magic-leap-seven-ages-of-man (2019) or floating in air in front of the user (Pietroszek et al. 2019). True to life experiences designed for AR viewing usually adapt the narrative itself to the limitation of AR displays' FOV. The field of view of user is larger than field of view of the AR device. The search may be directed with visual or auditory cues. Upcoming technological advances that increase the field of view in AR presentation will address this limitation.

When presented in virtual reality, volumetric filmmaking typically involves more than rendering of a volumetric capture of an actor. Sometimes, an entire set is reconstructed through a process of photogrammetry, creating a walkable immersive experience.

Interaction in Volumetric Film

Unlike traditional film or 360 video, a volumetric film is inherently an interactive, explorable, and three-dimensional experience (Fig. 1) that can be viewed from any point of the reality-virtuality continuum (Milgram et al. 1995). As an interactive medium, volumetric filmmaking differs *in essence* from the traditional filmmaking and 360 video that are passive media. Moreover, volumetric film attempts to directly simulate the visual input of the real world. It is conceivable that in a far-enough future, with sufficient technological advancements, human perception will be unable to distinguish the visual and auditory stimuli offered by a volumetric film from the visual and auditory stimuli provided by the reality itself. Such medium can no longer be called to "mediate."

Navigation

Navigating the volumetric film's world takes advantage of the techniques that were developed for virtual environments navigation and exploration, including real-time movement tracking, redirected walking (Sun et al. 2018), or various gaze-based or pointing-based teleportation techniques (Pietroszek 2018a). A scene in a volumetric film may limit the viewers' movement into predefined walkable area, or allow free-roaming within a world larger than the exhibition space. In the latter case, volumetric filmmakers typically try to avoid teleportation, since it takes the user out of the immersion and results in temporary disorientation right after the move. Recent advances in redirected walking, such as dynamic saccadic redirection-based redirected walking (Sun et al. 2018), promise that in a near future there will be no need to have the viewing space as large as the walkable scene space.

Interaction with Objects

Some volumetric films disallow any interaction between the viewer and the objects in the film, assuming the "direct cinema" approach, in which the viewer's presence in the scene should remain unnoticed as if the viewer was a *fly on the wall* (Nichols 1983). Few existing examples (Szilak and Tsiboulski 2018) break this "rule" and allow the user to interact with at least some of the objects in the scene. Interaction usually uses virtual hand metaphor (Pietroszek 2018b) through freehand tracking or a controller. No volumetric films to date use distal pointing or raycasting techniques for object selection and manipulation.

Interaction typically takes a form of object selection and *limited* manipulation of the objects, such as picking up a cup or rotating a dial. Actions are usually diagetic, and therefore exclude scaling or other modifications that are not possible in the real world, unless the story happens in a fictional world where such actions are possible. In few examples, the interaction is further enhanced by cloth or soft-body simulation applied to some objects (curtains, carpets, and bags) (Pietroszek et al. 2019).

Interaction with objects is often supported with pseudo-haptic or passive-haptic feedback. 3D printed versions of the film props may be used and tracked to provide close tactile resemblance of the prop's shape. Virtual walls and fixtures may be mapped to physical walls and fixtures to provide impenetrable navigation barrier or to increase immersion.

Embodiment

Similar to object interaction to date, very few volumetric films provide the viewer with an embodiment. Sometimes, the embodiment is limited to the rendering of hands (Szilak and Tsiboulski 2018). The embodiment may also be implicit, for example, as a reflection in the mirror that the viewer may look at. Whether the embodiment is implemented is often related to the point of view the story is being told from. In the first person stories, where the viewer is assumed to be one of the characters in the story, the embodiment may be provided (Szilak and Tsiboulski 2018). In the stories told from the third person perspective, the viewer embodiment is usually not provided.

Use of Spatial Mapping

Volumetric filmmaking often takes advantage of spatial computing, especially the 3D mapping of the environment. Some volumetric films use *augmented virtuality* (Milgram et al. 1995) by

mapping the set decoration and props onto physical elements of the installation. Volumetric captures may use physical chairs, tables, walls, or props to sit on, hide behind, jump onto, or lean on. For example, a chair displayed as a part of the set decoration of the current scene may be "good enough to sit in," to echo a line from an Ivan Sutherland's seminal "Ultimate Display" essay (Sutherland 1965), since it is mapped to a motion-tracked physical chair.

Volumetric Storytelling

The inherent interactivity of volumetric filmmaking affects its cinematography, montage, and the way the story ark is constructed. In traditional filmmaking, the story is told the way the director envisions it. The director starts by creating a unique vision of the screenplay, with its mood, color palette, pacing, acting style, cast, mise-en-scene, and, no less importantly, cinematography. Cinematography provides the director with an ability to decide a *point of view* that translates their vision onto the screen. Cinematography is designed in close collaboration between the director and the director of photography and consists of the choice of the shot sizes, camera angles, camera movements, and the spatial relationship between the actors' position and the camera (aka blocking). In postproduction, the director's vision is further revised through a myriad of montage techniques at the disposal of the film editor that affect the film's pacing, tempo, atmosphere, and the meaning and emotional impact of a sequence of frames through phenomena known as Kuleshov's effect (Barratt et al. 2016).

The language of 360 video builds upon the language of traditional filmmaking. However, due to the technical limitations of the current 360 cameras and their effects on human physiology and perception, only a subset of the cinematic language of traditional film finds its direct applications in 360 video production. For example, accelerated camera movements are not advisable, as they cause cyber sickness. Close-up is not possible since it results in the unnatural size of objects and actors. Cut disorients the viewer and is perceived as a jump cut rather than a time-compression mechanism. In response to the above challenges, 360 video expanded or modified the traditional cinematic language. Attention directing cues, replacing a cut with fade-out/fade-in, and long establishing takes that allow the viewer to orient themselves in the new environments are just few examples of how cinematic language evolved to accommodate the specificity of the 360 video as a storytelling medium.

Both traditional film and 360 video, once completed, constitute a finished piece of art. Even though the viewer's context and the passage of time impact its interpretation, the film remains essentially the same, a completed creative artifact.

A differentiating characteristic of a volumetric film is that it allows the viewer to perceive the story from a *point of view* of their choosing rather than the point of view chosen for them by the director of the film. The choice of shot sizes, camera angles, camera movements, and actors' positions versus the camera is now all up to the viewer. Moreover, it remains undetermined until the moment of viewing. In consequence, the watching process can no longer be described as passive. Every time the volumetric film is watched, or rather interacted with, the viewing is as different as would be the viewing of a traditional film that was reedited before every screening. The viewing process becomes the mode of interaction with the volumetric film, and the viewer takes on the role of the cinematographer and the editor.

Conclusion

While volumetric filmmaking is in its infancy, with only a handful of completed films, the technologies required to democratize and popularize this new-in-kind storytelling medium are becoming more and more accessible to independent filmmakers and visual artists. It can be expected that the volumetric filmmaking, once the technology matures, will find many applications in entertainment, education, communication, and many other domains.

Introduction

World of Tanks is a freemium team-based MMO involving armored tank combat. Developed by Wargaming, World of Tanks was released in North America on September 6, 2011.

Gameplay

World of Tanks is a team-based, action-packed, combat strategy game involving tanks from several different nations to fight against each other until one prevails in victory. The standard game mode within World of Tanks is known as "Random Battle." These battles consist of 15 versus 15 battles in which your objective is to either eliminate all opponents or capture the enemy base. Depending on the game mode, matches can last from 10–15 min, ending in a draw if one team does not eliminate the other.

World of Tanks is on desktop, consoles (e.g. Xbox and PlayStation), and mobile phones (World of Tanks, 2022). There are various game modes within World of Tanks such as Skirmishes, Ranked Battles, Training Rooms, and Special Battles. Skirmishes are oriented toward clan coordination in which you can battle just like normal random battles, but it is more of a team effort as you are playing with clan members rather than random players. Ranked Battles is a game mode offered periodically that allows players to compete against each other to gain chevrons. These chevrons allow you to advance throughout several divisions. After completing all the divisions, you will be assigned a rank of bronze, silver, or gold based on performance during division completion. Rewards vary depending on the rank you have earned. Training Rooms allow you to create a private match with friends, clans, or anybody to scrimmage, explore, or develop strategies for fighting. These rooms can be used for anything. Lastly, Special Battles are for tournaments and other Wargaming-sponsored events. Special Battles are typically available after you have participated in some sort of competitive events.

Playable characters

The game contains over 700 different tanks from many nations including Britain, China, Czechoslovakia, France, Germany, Italy, Japan, Poland, Russia, Sweden, and the USA (*General Guide: World of Tanks* 2022). These vehicles are rated using a tier-based system to pair them all up equally on the battlefield. There are also multiple tank classes to help categorize tanks. These classes are as follows: Heavy, Medium, Light, Tank Destroyer, and SPG (Self-Propelled Gun). Heavies are designed to be a more armored class that is meant to be in the front of the brawl. Light tanks tend to be used for spotting out maneuvering opponents with their incredible vision and speed. Medium tanks come up somewhere in the middle, being a hybrid of heavy and light classes. Tank Destroyers are your high-damage dealer tanks, bearing some of the most lethal armaments in the game. Finally, there is the SPG class which operates completely different in comparison to the other classes. SPGs are a long-range armament designed to be more of a support vehicle from afar. The tank shown in Fig. 1 is a light tank. This light tank is quite different from other tanks within the game because it utilizes wheels instead of tracks. This allows the vehicle to excel in speed and maneuverability.

There are many additional features within World of Tanks that allow for the enhancement and personalization of tanks. Some of these enhancements include crews and their trained skills, equipment, field modifications, ammunition, and camouflage. These upgrades and enhancements allow you to customize your tank to fit your playstyle and needs, allowing you to become more impactful on the battlefield.

Within World of Tanks there are also several currency systems such as Silver, Gold, Bonds, and

World of Tanks, MMO Strategy Freemium Game, Fig. 1 A light tank

Free Experience. Silver is the standard currency within the game. It can be earned from battles and challenges, and it can be used to purchase new vehicles, equipment, ammo, and more. Gold is the premium currency within World of Tanks. This is mainly used for retraining crews to operate different tanks, converting experience into free experience, purchasing premium vehicles, and demounting equipment. Although this premium currency can be purchased with real money, Gold is earnable through tournaments and challenges. Bonds are a very prestigious currency in World of Tanks, and they are earnable only in game through performance and challenges. Bonds are often given as a reward for performance in competitions and other high-level events, but they are also earnable in small amounts after every random battle. Bonds are mostly used to purchase special vehicles and bond equipment, which is the best equipment in the game (aka War bonds) (*World of Tanks War Bonds* 2022). Lastly, Free Experience can be earned slowly through matches or by converting normal experience earned in tanks with Gold currency into free experience. Free Experience can be used to unlock new tanks, modules, field modifications, and more – allowing players to experience a new vehicle without the tedious process of playing in a stock or underequipped tank.

Reception

After more than 10 years since the debut of World of Tanks, Wargaming claims that they have had over 60 million registered players and a peak concurrent player count of 1.1 million (*World of Tanks Announcements* 2022). However, the Russian and European game servers are much more populated than the North American server. Population on the North American server can typically be found around 10–20 thousand depending on the time of day.

Esports

World of Tanks debuted as an esports game as early as 2012. However, the only official World of Tanks esports tournaments were the

World of Tanks, MMO Strategy Freemium Game, Fig. 2 Professional team Natus Vincere "NAVI" winning the 2017 World of Tanks Grand Finals

Wargaming.net League, which took place over several regions including North America, offering a prize pool of $300,000 (Griffin 2014). While it was entertaining to many players, the competitive league did not draw as much attention as Wargaming had imagined and it has since been shut down. Figure 2 shows the professional team Natus Vincere "NAVI" winning the 2017 World of Tanks Grand Finals. The 2017 Grand Finals were the last year in which Wargaming.net League held the competitive league.

Although there is no longer an official Wargaming-sponsored esports league, Wargaming continues to host several large tournaments throughout the year, rewarding in-game currency or monetary prize pools.

Conclusion

Overall, World of Tanks is a fun and addicting spin on team-based fighting games. World of Tanks offers strategic combat, including legendary historical tanks from real life, to create a fun and entertaining battlefield for players to fight among each other.

Definitions

MMORPG = A Massively Multiplayer Online Role-Playing Game (MMORPG) is a video game that combines a role-playing game and a massively multiplayer online game.

Expansion = Extra purchasable content for a game released after the launch of the game. Each expansion can bring new characters, environments, and gameplay to the game.

MMORPG

World of Warcraft, often abbreviated as *WoW*, was released on November 23, 2004. The game was developed by Blizzard Entertainment for Microsoft Windows and macOS. It is the fourth game in the *Warcraft* series, although the first to be an MMORPG. It was given a Teen rating by the ESRB. *World of Warcraft* operates on a subscription service where players purchase times they can play in one-month, three-month, or six-month intervals.

WoW is an MMORPG that puts players into the world of Azeroth. *WoW's* core audience at the start were those who played the previous Warcraft games but branched out to many types of gamers as the game's audience grew larger. *WoW* currently has 12 playable classes, each with multiple different specializations that greatly vary the gameplay. Leveling through *WoW*, players don't encounter many enemy mechanics other than the odd spell and mob auto-attacks, however, as they advance through levels they also gain new abilities every level or two, and dungeons, as well as end game raids, have a lot of mechanics. The actual gameplay of each character is hotkey-based combat where players push keys on their keyboard to make their character do things. Although none of this is new now, it set the standard for MMORPGs (Thursten 2014) *WoW* has a reputation for a good soundtrack, whether it's a sad character piece or epic boss encounter music. There is also lots of variation in the music from zone to zone, and many have fond memories from the game's launch of playing through the initial levels and hearing the music (Messner 2020).

Expansions

WoW takes place on the planet of Azeroth mainly but also features planets such as Dreanor and Argus. The initial story of *WoW* has each player being a random adventurer, slowly growing in strength as they journey their way to the max level, at which point they would start going after and defeating strong "boss" mobs. After the initial variation of the game ended, Blizzard started making expansions that completely overhauled the classes, added a whole new leveling area, raised the level cap, and added in new leveling and end game content. The expansions also came with a new story, mostly revolving around large threats to the world, but never forgetting the foundation of the Warcraft franchise, which is the idea of the Alliance faction versus the Horde faction and the characters involved. *WoW* features a classic RPG leveling system, with the current cap being level 120. Although *WoW* has largely maintained the same visuals over the years, there have been

changes made to character models, improvements to the art style, and every new expansion comes with new environments that helped vary up the gameplay and the world. The gameplay changed in every expansion, from the slower pace of the original to the faster pace of today. *WoW*'s gameplay is drastically different from when it launched.

Interface

WoW's interface starts with a single action bar in the bottom right to hold spells and abilities, to the right of that is a range of buttons, including the character screen and the help menu, to the right of that is the bag slots where the bags a player has on them and how much space is in them. In the upper left is the health and resource bar, and finally in the upper right is the mini-map. There is also the option of adding in three more action bars if players run out of space (Fig. 1).

WoW is one of the most well-known games ever released, and scored very highly by fans and critics alike. It is also one of the most played games of all time (Fbalestra 2015).

Controversies

One of the biggest controversies in the community was the final raid of the Cataclysm expansion (Wolfshead 2011), which had a small eight boss count, and ended with two of the most hated raid fights in the game's history. Another controversy was the announcement of the Mists of Pandaria expansion (Cirino 2012), this was controversial because many players thought it was a bit weird to go from killing a giant dragon that wanted to destroy the planet, to fighting alongside a bunch of panda people and learning about unimportant things like farming and peace. Since the day of launch, *WoW*'s biggest weakness has been its servers. The issue is that the servers were made for a game that would cap out at about 200,000 players. Considering that *WoW* peaked at around 12 million players, it's easy to see why even to this day, despite the fact that Blizzard has spent more than a decade trying to fix it, if a large group of players gets on a busy server, the game will start to have issues.

Similar games to *WoW* include *Everquest* and *RuneScape*. Both of these games have similar designs and concepts (especially *Everquest*), but

World of Warcraft, a MMORPG with Expansions, Fig. 1 World of Warcraft interface.

WoW definitely set itself apart with its better graphics and less punishing systems.

World Representation in Artificial Intelligence

Definition

World representation is used as an umbrella term to encompass any method allowing the Artificial Intelligence (AI) agents to know about the world they are operating in. This includes, but is not limited to, navigation data, knowledge representation, and spatial reasoning, to name only a few. Globally, these techniques revolve around organizing the information defining a virtual world into specific data formats, designed to be easy to process for in-game AI agents. The agents then access that data and process it to accomplish the behaviors or computations needed by the game.

Introduction

Video games allow human players to immerse themselves in virtual worlds. The level of interactivity of these worlds varies from one game to another, but in all cases, players can rely on their own senses to explore and interact with the virtual environment of the game.

AI agents, on the other hand, do not have access to the same perception and reasoning skills as human players. Emulating human senses is a possibility, and is especially common in robotics AI, where robots will use sensors to recognize the environment around them. However, in the case of video games, this process is too costly in terms of both calculation and memory. This makes it unsuitable for game AI agents, which can be many to share the same processing power. As an alternative, the solution is to use dedicated formats of data to represent elements of the virtual world. The goal of these formats is to be efficient to access and easy to process for AI agents. The organization of that data is what makes up world representation.

This chapter will present an overview of multiple techniques that are used for world representation. First, we will cover environment knowledge, going from navigation data to interactive objects, which allow an agent to navigate in the environment and interact with elements contained in it. We will then move on to spatial reasoning, which involves more complex computations on the environment data in order to take some intelligent decisions with regard to an environment's layout. In opposition to globally shared environment data, we will then cover individual agent knowledge, which comprises perception and some forms of imperfect knowledge. Finally, we will go over multi-agent knowledge, which is necessary to achieve intelligent behavior for a team of multiple characters.

Environment Knowledge

In order to be able to navigate and interact with an environment, the first step for AI agents is to know how that environment is structured. Navigation data allows them to know about navigable terrain, move around without hitting obstacles, and find suitable paths from one location to another. In addition to the navigation data, environment markup information allows the AI agents to achieve advanced traversal and interact with the objects.

Navigation Data

Navigation data is an abstract representation of the game world, containing only the sections that can be navigated on. The specific representations can vary, but internally all of them boil down to a graph between different locations. A pathfinding system can then search the graph to compute paths between positions in the game world. This is ultimately what allows the AI agents to know how and where to navigate through the game world. This section will focus on the data representation for 2D and 3D navigation.

2D Navigation

2D navigation data is used to represent walkable surfaces, such as floors. Common representations include navigation grids, waypoint graphs, or navigation meshes. These will be covered in this section.

A navigation grid divides the game world into a grid composed of cells of a fixed size (Yap 2002). Each cell is marked as either blocked or unblocked, based on whether or not it is possible or not for an agent to navigate on the terrain in that cell. Navigation is then achieved by finding paths that go through connected cells.

Waypoints graphs represent the game world as a graph of connected points. Waypoints are placed or generated in the world, as a way to discretize the navigable surfaces. A connection between two waypoints, means there is a way to navigate directly from one to the other (Liden 2000). Each waypoint represents a valid position where an agent can decide to go. Navigating through a waypoint graph is then done by going from one waypoint to another through the connections between them.

Navigation meshes are probably the most common navigation representation in modern games. They divide the 2D navigable space as convex polygons. Each polygon is a node in the search graph, while common edges between two polygons represent an edge in the graph (Snook 2000). Navigation meshes are more complex than navigation grids or waypoint graphs. Because navigable terrain is divided as convex polygons, these polygons can represent areas of variable size and shapes. Navigation meshes can be authored manually or generated automatically by analyzing the collision data of an environment.

3D Navigation

While the navigation data in most games will be limited to 2D navigable space, some games require 3D representations, for movement such as swimming or flying. The number of available axes for motion is the main factor. Additionally this can also be a viable way of representing sound propagation, as mentioned in section "Perception". Representations for 3D navigation include navigation grids and sparse voxel octrees.

Navigation grids work the same way in 3D than they do in 2D, with the exception that a cell is a cube instead of a square. The whole environment can be represented using blocked or unblocked cells, similarly to 2D grids. Because of the nature of 3D space, the number of cells quickly grows, meaning that this can be very memory intensive. The main challenge revolves around finding a way to make the representation more sparse (Sturtevant 2011).

Armored Core V uses procedural generation to create their 3D navigation grid. The game space is filled with a large number of cubes, which then needs to be reduced. This is done through simulated annealing, which combines adjacent cells together by keeping as big cuboid shapes as possible (Okamura 2011).

As an alternative to 3D navigation grids, sparse voxel octree can be used to represent the 3D space. Instead of a grid, each cube of space is

divided into eight children, recursively until a minimum size, and organized as a tree. This results in a representation that is more optimized than a simple 3D grid (Brewer 2017).

Choosing a Representation

Ultimately, all of those formats are a valid way to represent the space in which an AI agent will need to navigate. Selecting the best representation will come down to several factors, such as memory, performance, ease of use, and the type of environment the game will use. Articles such as Sturtevant (2013) and Tozour (2004) explain in detail the advantages and shortcomings of each approach.

Environment Markup

Navigation data allows agents to have information about where they can navigate in their environment. However, games often have complex environments that require advanced interactions in addition to moving around. In those cases, environment markup can be used alongside the navigation data in order to provide information to the AI agents about how they can interact with the environment. This can be used for advanced navigation such as doors or ladders, to find good positions or covers during combat, or to interact with objects in the environment.

Advanced Navigation

There are many ways in which a game level can be composed of navigable areas which are not directly connected to one another. AI agents can go from one area to another by jumping, going through doors, or other types of interactions (Hancock 2002; Reed and Geisler 2003).

These types of connectivity require setting up some environment markup to indicate the connected positions from one area to another. Such markup needs to contain some information detailing the type of interaction. When pathfinding, it becomes possible to know a connection exists between two different areas. Upon reaching that connection, based on the type of interaction necessary, a special behavior can be performed to reach the desired area.

Tactical Positions

Many games involve some form of combat, which tends to depend on finding correct tactical positions from where to fight. A way to find good tactical positions is to have suitable candidate positions as part of the environment markup. A straightforward way to do this is to manually add some markup in the environment where there are suitable tactical positions.

A more clever way to represent tactical positions might be to reuse navigation data. This is one of the strengths of waypoint graphs, as tactical information can be embedded inside the waypoints to allow them to become valid tactical positions (Liden 2002).

As this type of markup editing can easily become time sensitive, methods that can automatically generate tactical positions are an interesting alternative. As this does not represent the environment markup, this will be covered in section "Terrain Analysis."

Covers

A good tactical position often involves hiding or covering behind a solid surface, rather than finding a position in plain sight. For this reason, cover is a very common game ingredient when it comes to game in AI. Cover selection is resolved using similar selection algorithms than tactical positions.

However, cover markup in itself will be different because more information is necessary (Darken and Paull 2006). Covers are tied to physical objects or parts of the environment, which give protection in specific angles and directions. They can also permit or not to fire in certain directions while partially hidden, or necessitate some advanced navigation in order to reach or enter them.

Smart Objects

Any other type of interaction will generally involve some external objects that can vary from one game to another. In those cases, smart objects (Kallmann 2001) are the standard solution. These objects are called smart because they contain the information about how the character should

interact with them, via some form of script or internal data. This allows for some flexible and scalable interactions where an AI agent can detect interactive objects around them, and figure out how to use them by interfacing with the object.

Spatial Reasoning

With tactical positions and cover object markup, section "Environment Markup" introduced the notion that in addition to knowing how to navigate and interact with their environment, AI agents need to make intelligent decisions about where to go and what to do once they get there. Up to now we have covered methods to achieve this which involve annotating a game level with additional information. Spatial reasoning, on the other hand, regroups techniques that aim to identify information about the environment through computation. This section will cover multiple approaches to spatial reasoning.

Influence Maps

Influence maps are used to identify areas of the game world that are subject to a certain influence. In this context, influence is an abstract measure of a game mechanic such as threat value, territory ownership, or any other type of information that can be tied to space and change over time. Influence can then be used in order to know how good a given position is or in order to find the best position to do something (Tozour 2001).

The first step to building an influence map is to discretize the environment into smaller areas. The most straightforward method is to divide using a grid approach, similar to the navigation mentioned in section "2D Navigation." Each cell in the grid has a given value of influence at a given time, which can be accessed by the AI as a source of information.

In order to compute the value of influence at a given location, influence is propagated from various sources. For instance, when computing threat influence, influence can be propagated from an enemy's position in a radius around them, with a given decay function. Propagated influence values can then be added (or subtracted for opposing influences) to result in a final value at each position. Because game worlds are constantly changing, influence values need to be recomputed periodically.

The main downside of influence maps is that they tend to be expensive computation wise. Potential solutions include using a continuous, rather than discrete, approach to reduce the amount of computations (Lewis 2015), or cleverly combining precomputed influence map templates to efficiently obtain results (Mark 2015).

Terrain Analysis

Terrain analysis refers to any technique aiming to reason about the terrain in a game in order to find certain interesting properties. The goal is generally to find some positions that are good to go to perform certain types of actions, or in the opposite, which are good targets for certain types of actions. As the applications for terrain analysis are many, this section will only cover some of them as examples.

It is important to note that in all of the following examples, the amount of computation required to obtain results is quite significant. This means terrain reasoning is usually too expensive to perform while the game is running, and is instead done during a preparation phase using a level's geometry data. The pre-computed results are then stored in a specific data format that is easily accessible during the game.

Identifying Choke Points

Choke points make for excellent positions for the AI agents to plan an ambush, or defend some territory from an external invasion. However, finding choke points requires some deep understanding of the level's layout and navigable space. Perkins (2010) describes an algorithm to find choke points based on region adjacency.

Starting from the obstacle polygons in a level, this technique aims to divide the level into regions. A region is defined as a navigable space that is not blocked by an obstacle. The goal is then to identify choke points, which if blocked, would either merge two obstacles together, or prevent one region from being reachable by another.

Finding Combat Positions

Section "Tactical Positions" went over not only on the idea of annotating levels with tactical position data but also on the necessity of determining what positions are good attack positions. Liden (2002) describes methods to use a waypoint graph to automatically find tactical positions.

The idea is to reuse the waypoints that are used for navigation as a source of information to find tactical positions. Because all the potential positions are known ahead of time, it is possible to precompute information about them, such as the visibility from one point to another. This information can then be used at runtime to find positions that are protected from one another, or to execute flanking tactics.

Finding a Sniping Position

In shooter games, some positions are clearly better than others to engage in ranged combat with enemies. Especially, in the case of snipers, good positions involve having visibility towards other parts of the map, while also being difficult to reach. der Sterren (2001) describes the steps to find good sniping positions using those types of criteria.

A sniping position is essentially a specific case of a combat position. Thus, once again, reasoning using waypoint data is possible. The different qualities that make a good position can be expressed as numerical values, and obtained through the waypoint graph data, such as luminosity, line of sight to another waypoint, and so on. A score can then be computed for each position, and the highest rated positions represent good sniping positions.

Finding Covers

Covers are an especially complex, specific case of combat positions. Paull: Online Offline cover finding presents methods to find covers based on waypoint data, cover data and runtime processing. For each agent, by evaluating a fixed amount of candidate waypoint positions around the agent, these candidate positions can be ordered based on visibility, and ability to peek-out.

Tactical Query Systems

As a follow-up to terrain reasoning, modern game engines have been introducing tactical query systems as an alternative to find positions during a game's execution. Popular examples of these systems include Crytek's Tactical Point System (Jack 2013) or Unreal Engine's Environment Query System (Zielinski 2013).

The resolution of a query involves multiple steps. First, a region of the environment will be sampled to generate a large number of candidate positions to be evaluated. Then each position will be evaluated by tests aiming to filter and score the candidate points. The goal of filtering is to eliminate the candidate positions that are absolutely unsuitable, such as a point inside of a wall, or a point in a different room. The points that are not filtered will be attributed a total fitting score based on the criteria evaluated. A position receiving a high score might be easy to navigate to and offer a good tactical advantage. Finally, the best, or several of the best positions can be selected as the result of the query. More details about the steps of resolving a query can be found in Johnson (2017).

Imperfect Individual Knowledge

Till date, this chapter has covered different approaches to give the AI agents global information about the game world. However, in order to have credible AI agents, it is often common to have them know only about subsets of the environment. Similar to real humans, these AI agents should only be aware of the parts of the environment they have been exposed to. This is called imperfect individual knowledge.

Imperfect individual knowledge uses an architecture modeled on the human brain. As a first layer, AI agents have a form of perception similar to human senses, in order to identify what they are able to detect or not. Perceived information is then stored in a memory layer. That memory becomes the knowledge base allowing the AI agents to take decisions (Isla et al. 2001).

Perception

Even though humans have access to five senses, only three of them are commonly used to model AI perception. Sight is used to see elements of the environment, hearing is used to react to noises, and touch is used to react to collisions.

Vision is mainly modeled using ray casting from the agent's position to some other entities in order to test if they are being detected. Because raycasts are expensive, this is usually combined with a vision detection volume. Only entities currently in the detection volume will be tested for raycasts, thus reducing the computation cost. Different volumes of different shapes can be alternated or combined depending on the game's needs (Walsh 2015).

Depending on the type of game, hearing can be simple or complicated. For some games, hearing can be modeled using only distance tests. Hearing capacity is modeled given a certain range, and any sound generated inside that range will be heard by the AI agent. Other types of games will require a more accurate model of hearing. A way to achieve this is to reuse the concepts of 3D navigation to represent hearing (Walsh 2015). In that case, hearing is resolved by testing for 3D reachability from the source of the sound to the agent.

Compared to sight and hearing, touch is normally fairly easy to implement. Since most games already contain a physics engine, that engine's collision detection can be reused to model touch. By reacting to collision callbacks, an AI agent can react to something touching them, based on the source of the contact.

Memory

Information that is perceived can be stored in a memory. From there on, the agent will be able to reason based on the content of that memory, rather than on information that is globally available from the game world. This leads to agents working with imperfect knowledge based on what they have perceived, which is closer to how humans behave.

Probably the most currently common format to store an AI agent's working memory is to use a blackboard (Isla and Blumberg 2002). As the name implies, a blackboard is a shared repository of knowledge, where variables can be added, modified or read by any AI system. This allows easy access to any information the AI should currently know, while also reducing strong coupling between different AI systems. Any perceived information can be added to the blackboard, to be used at the time of decision-making.

Stimulus Knowledge

Section "Perception" covered different types of perception, while section "Memory" explained how detected information can be stored in memory for an AI agent. However, detecting events that happen in the game is only a first step. With a lot of characters doing different things, a player affecting the world, there can be a lot of stimuli being detected by the AI agents. For this reason, some form of filtering and prioritizing is generally necessary to make sure agents are not overwhelmed by the amount of stimuli, meaning spending too much performance on detection, or reacting and acting with regards to stimuli in a way that seems unintelligent.

Simple examples of filtering involve ignoring stimuli from allied sources, or ignoring some stimuli based on the current level of alert. Additionally, some things happening in the game are definitely more important than others, meaning that there must be some sort of priority system. Miles (2013) and Welsh (2013) feature good examples for both filtering and prioritizing.

Probability Occupancy Grid

For games where fighting against enemies is a core element of gameplay, proper consistency of threat management data is primordial. AI agents must behave according to the information they have detected, as threats are detected, then lost, and discovered again.

A good technique to model credible search behaviors based on accurate data is to use a probability occupancy grid (Isla 2006). Probability occupancy grids share some similitudes with influence maps, covered in section "Influence Maps," as they rely on propagating data along a grid representation of the world. When a threat goes from being detected to undetected, the last known position can be retained on the grid. Then,

as time passes, the potential displacement of the threat can be propagated on the grid from the last known position. This allows the modeling of plausible candidate hiding positions that can be investigated.

Agent Coordination

Section "Imperfect Individual Knowledge" covered imperfect knowledge in the context of an individual agent acting alone. However, games will most likely contain more than one AI agent, and AI agents will need to consider the information about each other. When other agents are enemies, threat data as covered in section "Probability Occupancy Grid" will usually be sufficient. In the case of AI agents acting as a team, some form of information sharing is necessary to make them appear to work together.

Orchestrated AI

One approach is to use an orchestrated AI (der Sterren 2002). In this situation, all decision-making relating to what the AI agents should do as a group is the responsibility of a separate AI module. That module will either use perfect knowledge or the union of all agents' imperfect knowledge to determine where agents should position themselves or which member of the group should be selected to do a specific action.

There are multiple ways to communicate between that group AI layer and individual agents. The group can give direct commands to the individuals, or update their individual knowledge in some way to allow them to take the proper decision on their own based on what was decided by the group (Reynolds 2002).

Emergent AI

On the other hand, agents can take all of their actions on their own. In this situation, they will need to know about what information the other agents have, in order to maintain at least an illusion of coordination between agents.

A very simple solution is to reuse the concept of blackboard from section "Memory". In addition to having an individual blackboard to store an agent's current knowledge, an additional blackboard can be used to share knowledge between agents. Each agent can then add the information they want to share to that blackboard, and everyone can access it to have the most up to date information.

Another solution is to use a trigger system (Rabin 2002) to propagate the information to agents. Triggers can be set up to send events on reaction to some actions the player is taking, some changes in the environment, or simply be sent deliberately from one AI agent to others. Once a trigger happens, each agent can decide what to do upon receiving the information. It is possible to react immediately upon reception, or to store the information in some form of knowledge representation in order to take a decision about it later.

Discussion

This chapter provided an overview of many different techniques that can be used to give AI agents information about the environment they are evolving in. This section discusses in more detail the current usage trend of these techniques for modern games, as well as what kind of challenges can be expected for future games when it comes to world representation.

A good portion of the techniques covered in this chapter are standard and well spread among games. For example, close to all games feature some sort of navigation, and thus will make use of navigation data. It is now very common to have interactive objects in game environments, which can be implemented as smart objects. Most modern games aim to have credible AI that does not appear to cheat, thus relying on perception and individual knowledge. These are example of techniques that have been used for a long time, are well understood and can be added to any game that needs them without too much trouble.

On the other hand, the other techniques are less frequently used, which can be explained by multiple factors. Finding choke points makes a big difference for a strategy game, but may not have such a big impact on other genres. Influence maps add an additional layer of information to the

game, but come with a cost both in terms of development time and performance. A probability occupancy grid adds some amount of intelligence to an AI performing a search, but may not be needed outside of stealth games. The richness of cooperative behavior using squad AI can be enticing to have an impressive AI, but managing the complexity between group and individual AI can quickly become complex. These are examples of techniques that are more specialized, and come with a certain cost, meaning they should only be implemented if there is a strong need for it.

These less-used techniques highlight the fact that there is rarely one single optimal solution when it comes to game AI. Developing and integrating a world representation technique incurs some costs in terms of both development time and hardware resources, such as processing power or memory. Choosing the appropriate world representation techniques to use should be done by considering what is needed for the game being developed.

Regarding newest and future development for world representation in games, two different factors are having an impact. On one hand, hardware is getting more and more powerful, meaning that problems that were limited by performance issues can be more accessible. On the other hand, games are getting bigger and more complex, meaning that the amount of information to be tracked is bigger than ever.

Access to more performance intuitively makes expensive techniques more accessible. However, the biggest impact is on techniques such as navigation data generation or terrain reasoning, which are traditionally done as a preparation pass to output precomputed data that will be used by the game. Access to more performant hardware means that such techniques can gradually migrate to runtime solutions. Precomputed navigation data is still the norm, but runtime navigation data is becoming more common. Similarly, tactical query systems can perform at runtime some of the operations that were initially reserved to terrain reasoning.

At the same time, games are scaling both in size and complexity, so performance remains a limitation. However, these limitations tend to manifest in different ways now that techniques are evolving. Rather than relying on raw processing power, games are being clever with resource management by using systems such as multithreading, asynchronous updates and streaming. Naturally, the central nature of such systems means that there is also an impact on world representation. Systems should now handle objects being loaded or unloaded because of streaming, as well as information being accessed concurrently.

Conclusion and Discussion

This chapter presented many different techniques allowing the AI agents to know about the environment they operate in, even though they do not have access to the same senses and reasoning as humans do. Navigation data combined with environment markup allows them to know how to navigate in the environment, as well as how to interact with it. Spatial reasoning allows them to understand the spatial layout of an environment, and to take intelligent decisions based on it. Imperfect knowledge allows individual AI agents to act credibly based on the information they have perceived themselves. Finally, knowledge about other AI agents allows them to have some mutual awareness and perform some coordinated actions.

Some of these techniques are broadly used, others are more specific, meaning understanding what problems they solve is primordial to choosing which techniques to use. As technology progresses, some techniques that were difficult to implement because or performance constraints become more available, even allowing some runtime evaluation techniques. Simultaneously, games continue to become more complex, meaning that performance is still an issue, and techniques have evolved to support streaming and multithreading. As games themselves will certainly continue to evolve, new needs for world representation will continue to appear leading to a corresponding evolution of world representation techniques.
